Some transmission designs do not rely on an accumulator for shift quality; rather, they have a restrictive orifice in the line to the servo or multiple-disc pack's piston. This restriction decreases the amount of initial apply pressure but will eventually allow for full pressure to act on the piston.

Several transmissions use servo units that also work as an accumulator. These units are typically used with the intermediate band and for upshifts out of second or third gear. This servo/accumulator unit actually keeps the band applied during the initial engagement of the clutch pack. As the clutch becomes more engaged, the band is released. This action prevents the harsh engagement of the upshift.

Other designs have multiple accumulators built into the servo assembly. Doing this allows the accumulators to respond directly to the action of the servo.

Shift Timing

For non-electronic systems, shift timing is determined by throttle pressure and governor pressure acting on opposite ends of the shift valve. When a vehicle is accelerating from a stop, throttle pressure is high and governor pressure is low. As vehicle speed increases, the throttle pressure decreases and the governor pressure increases. When governor pressure overcomes throttle pressure and the spring tension at the shift valve, the shift valve moves to direct pressure to the appropriate apply device and the transmission upshifts.

Gear Changes

An automatic transmission will change gear ratios and direction automatically or at the command of the driver. Automatic shifting allows for forward gear ratio changes in response to engine speed and load. And, in the case of electronically controlled units, in response to the PCM's interpretation of operating conditions. The transmission will not automatically move into park, reverse, or neutral. The driver makes these gear selections. The driver can also select certain forward gears. The forward gears available for manual selection vary with each transmission model.

A discussion on how gear changes are made is a summary of the operation of the transmission's components. Keep in mind, the way a particular transmission operates depends on its construction and components. This discussion is based on a common four-speed design using a Simpson gearset and an add-on overdrive planetary unit **(Figure 41–75)**. There are no electronic controls mentioned in this discussion because it is important for you to understand how the gearset responds to the various hydraulic components in a transmission before you can understand how electronics improve the performance of a transmission. The clutch, brake, and band application for this typical transmission is shown in **Figure 41–76**. Refer to both figures as you read the following discussion.

Park/Neutral

When park is selected, the shift linkage moves the park pawl or lever into the park gear, located on the output shaft or final drive shaft **(Figure 41–77)**. The shift linkage also moves the manual shift valve to block the fluid passages to the clutches and bands. No member of the gearset receives input torque and no member is held, therefore there is no output. Fluid flows to feed the torque converter and to lubricate and cool the transmission. In the neutral position, all of the same conditions of the park mode exist, except the park lever is not engaged to the park gear.

Reverse

When reverse is selected, the manual shift valve is moved and fluid is sent to the front clutch and the low/reverse band. The pressure of the fluid is greater than mainline because boost pressure is added to the circuit at the pressure regulator valve. This added

pressure provides good clamping and prevents clutch and band slippage.

The front clutch locks into the drive shell and the sun gear becomes the input. The low/reverse band holds the rear planetary carrier. The sun gear rotates in a clockwise direction and drives the rear planet pinions in a counterclockwise direction. The pinions then cause the rear ring gear to rotate in a counterclockwise direction. Since the rear ring gear is splined to the output shaft, the output shaft rotates in the opposite direction as the input shaft.

While the transmission is in reverse, the separate overdrive planetary gearset is in direct drive. This is accomplished by the engagement of the overdrive direct clutch that locks the sun and ring gears together. This clutch also provides for engine braking in reverse and the forward reduction gears.

Drive Range

When the shift linkage is moved to the D position, the manual shift valve allows fluid flow to engage the rear clutch. Fluid pressure is also directed to the shift valve. When the vehicle is stopped and in first gear, the various gear shift valves are closed by spring tension.

Input is transmitted through the rear clutch to the front ring gear in a clockwise direction. The front carrier is splined to the output shaft and is held by the weight of the vehicle at the drive wheels. The front ring gear drives the front planet pinions in the same direction. The planets, in turn, drive the common sun gear in the opposite or counterclockwise direction. The rear carrier is held by the one-way clutch as the planet pinions attempt to rotate the rear ring gear, they walk the rear carrier in a counterclockwise

direction. The ring gear is splined to the output shaft and the output is in the same direction as the input but at greater torque. This is first gear.

While the transmission is in the forward gears, the separate overdrive planetary gearset is in direct drive. The direct drive mode keeps transmission output connected to the input of the transmission. This unit also uses a one-way clutch that locks the shaft connecting the two planetary units to the output shaft.

This mode of operation will continue as long as the one-way clutch is locked or until the 1-2 shift valve forces an upshift. The clutch will remain locked until engine torque is released from the planetary unit or when the inertia of the vehicle is coasting and driving the planetary unit by the output shaft. The rear carrier rotates in a clockwise direction with the output shaft. This releases the one-way clutch. Since there is no longer a reactionary member, the transmission is effectively in neutral.

As the vehicle accelerates in first gear, the automatic movement of the shift valve controls progressive shifts through the other forward gears. As the vehicle moves forward, throttle pressure builds and helps the shift valve spring keep the valve in position. As output shaft and vehicle speed increases, governor pressure builds. Once governor pressure is great enough to overcome the combined pressure of the spring and throttle pressure, the 1-2 shift valve is pushed open. Fluid is directed to the front band, which holds the driving shell and the sun gear.

The rear clutch is still engaged and drives the front ring gear and front planet pinions in a clockwise direction. The front planets drive the front carrier and the output shaft with some reduction. This is second gear. The rear planetary unit is ineffective because the rear carrier freewheels in the one-way clutch.

As the output shaft speed increases, governor pressure continues to build. Much more pressure is needed to move the 3-2 shift valve than was required to move the 1-2 shift valve. This is because it is held by a heavier spring tension and throttle pressure. Once governor pressure is great enough to overcome the pressure holding the 2-3 shift valve, the shift valve moves and opens the fluid circuit to the front clutch. At this time, fluid flow to the front band is stopped and the sun gear is released. The rear clutch remains applied and input is applied to the front ring gear through the rear clutch and to the sun gear through the front clutch. The front carrier is locked between these two input members and drives the output shaft at the same speed as the input. This is third gear.

To move the 3-4 shift valve requires more pressure than the 1-2 and 2-3 shift valves. Again this is due to high spring tensions. Once vehicle and output shaft is great enough to increase governor pressure enough to move the 3-4 shift valve, fluid is sent to the overdrive clutch. When this happens, the 2-3 shift valve remains open and direct drive output is available to the overdrive planetary.

When pressure is first applied to the overdrive clutch, the overdrive clutch piston compresses the spring for the direct clutch and releases it. Then the pressure engages the overdrive clutch and locks the sun gear to the transmission housing.

Automatic Downshifting

Upshifts occur because governor pressure builds up enough to overcome the spring tension and the throttle pressure on a shift valve. Down shifting occurs when governor pressure decreases to the point where it can no longer overcome those pressures. Down shifting will also occur when throttle pressure has increased and is able to overtake governor pressure.

During a coast condition, governor and throttle pressure decreases as the vehicle slows. The transmission will begin its downshift sequence by responding to these lower pressures. Since the 3-4 shift valve has the highest spring tension on it, it will be the first shift valve to move with the decreased governor pressure. The last shift valve to move is the 1-2 shift valve because the spring tension on it is the lowest of all shift valves.

Forced downshifts occur when the throttle is quickly opened during acceleration and increases throttle pressure. If governor pressure is not great enough to overcome the combined pressure of the shift valve spring and throttle pressure, the shift valve will close. This drops the transmissions into the lower gear until governor pressure builds up enough to overtake the pressure on the shift valve.

Manual Low

When the driver selects a gear other than D, the manual shift valve controls the action of the other shift valves. By selecting a gear, the driver tells the transmission to stay in that gear or start off in that gear. The latter is often used when initiating movement when the vehicle is on ice or other slippery surfaces.

Basically the movement of the gear selector into a manual gear inhibits the shift valve. When the driver selects Drive 2 while the transmission is in third gear, the transmission may downshift regardless of vehicle and engine speed. The manual shift valve cuts off line pressure to the 2-3 shift valve and the transmission drops to second gear.

SUMMARY

- The torque converter is a fluid clutch used to transfer engine torque from the engine to the transmission. It automatically engages and disengages power transfer from the engine to the transmission in relation to engine rpm. It consists of three elements: the impeller (input), turbine (output), and stator (torque multiplier).
- Two types of oil flow take place inside the torque converter: rotary and vortex flow.
- An overrunning clutch keeps the stator assembly from rotating in one direction and permits overrunning when turned in the opposite direction.
- A lockup torque converter eliminates the slip that takes place between the impeller and turbine at the coupling stage of operation.
- Planetary gearsets transfer power and alter the engine's torque. Compound gearsets combine two simple planetary gearsets so that load can be spread over a greater number of teeth for strength

and also so the largest number of gear ratios possible can be obtained in a compact area. A simple planetary gearset consists of a sun gear, a carrier with planetary pinions mounted to it, and an internally toothed ring gear.

- Planetary gear controls include transmission bands, servos, and clutches. A band is a braking assembly positioned around a drum. There are two types: single wrap and double wrap. Simple and compound servos are used to engage bands. Transmission clutches, either overrunning or multiple disc, are capable of both holding and driving members.
- There are two common designs of compound gearsets, the Simpson gearset, in which two planetary gearsets share a common sun gear, and the Ravigneaux gearset, which has two sun gears, two sets of planet gears, and a common ring gear.
- Some transmissions rely on two simple planetary gearsets connected in tandem.
- Lepelletier gearsets rely on a combination of Simpson and Ravigneaux gearsets.
- Many Honda transaxles do not use a planetary gearset; rather, constant-mesh helical and square-cut gears are used similar to that of a manual transmission.
- The operation of most CVTs is based on a steel belt linking two variable pulleys.
- Many hybrid vehicles have CVTs that rely on a planetary gearset and two electric motors rather than pulleys and belts.
- An automatic transmission uses ATF pressure to control the action of the planetary gearsets.
- ATF fluid pressure is regulated and directed to change gears automatically through the use of various pressure regulators and control valves. The transmission's pump is driven by the torque converter shell at engine speed. The purpose of the pump is to create fluid flow and pressure in the system. Excessive pump pressure is controlled by the pressure regulator valve. Three common types of oil pumps are installed in automatic transmissions: the gear, rotor, and vane.
- The valve body is the control center of the automatic transmission. It is made of two or three main parts. Internally, the valve body has many fluid passages called worm tracks.
- The purpose of a valve is to start, stop, or to direct and regulate fluid flow. Generally, in most valve bodies used in automatic transmissions, three types of valves are used: check ball, poppet, and, most common, the spool.
- To prevent stalling, the automatic transmission pump has a pressure regulator valve normally located in the valve body. It maintains a basic fluid pressure. The valve's movement to the exhaust position is controlled by calibrated coil spring tension.
- Bearings that take radial loads are called bushings and those that take axial loads are called thrust washers.
- The gaskets and seals of an automatic transmission help to contain the fluid within the transmission and prevent the fluid from leaking out of the various hydraulic circuits. Different types of seals are used in automatic transmissions; they can be made of rubber, metal, or Teflon.
- Three major types of rubber seals are used in automatic transmissions: the O-ring, the lip seal, and the square-cut seal.
- Three types of sealing rings are used in automatic transmissions: butt-end seals, open-end seals, and hook-end seals.

ELECTRONIC AUTOMATIC TRANSMISSIONS

OBJECTIVES

- Describe what determines the shift characteristics of each selector lever position.
- Identify the input and output devices in a typical electronic control system and briefly describe the function of each.
- Diagnose electronic control systems and determine needed repairs.
- Conduct preliminary checks on the EAT systems and determine needed repairs or service.

- Inspect, test, and replace electrical/electronic sensors.
- Inspect, test, and replace actuators.

Electronic transmission control provides automatic gear changes when certain operating conditions are met. Through the use of electronics, transmissions have better shift timing and quality. As a result, the transmissions contribute to improved fuel economy, lower exhaust emission levels, and improved driver comfort. Although these transmissions function in the same way as earlier hydraulically based transmissions, a computer determines their shift points and the shift quality. The computer uses inputs from different sensors and matches the information to a predetermined program.

Today's electronic transmissions also have self-diagnostic capabilities and can accurately control mainline pressure, apply pressures, TCC operation, and engine torque during shifts. Electronically controlled transmissions typically do not have governors nor throttle pressure devices. The control unit monitors and controls

the action of shift solenoids **(Figure 42–1)**. The solenoids do not directly control the transmission's clutches and bands. The clutches and bands are engaged or disengaged in the same way as hydraulically controlled units. The solenoids simply control the fluid pressures and do not perform a mechanical function.

In an electronic automatic transmission (EAT) system, there is a central processing unit, inputs, and outputs **(Figure 42–2)**. Often the central processing unit is a separate computer designated for transmission control. The computer receives information from various inputs and controls the solenoids that control hydraulic pressure and fluid flow to the apply devices and to the clutch of the torque converter. This computer may be the **transmission control module (TCM)**, the body control

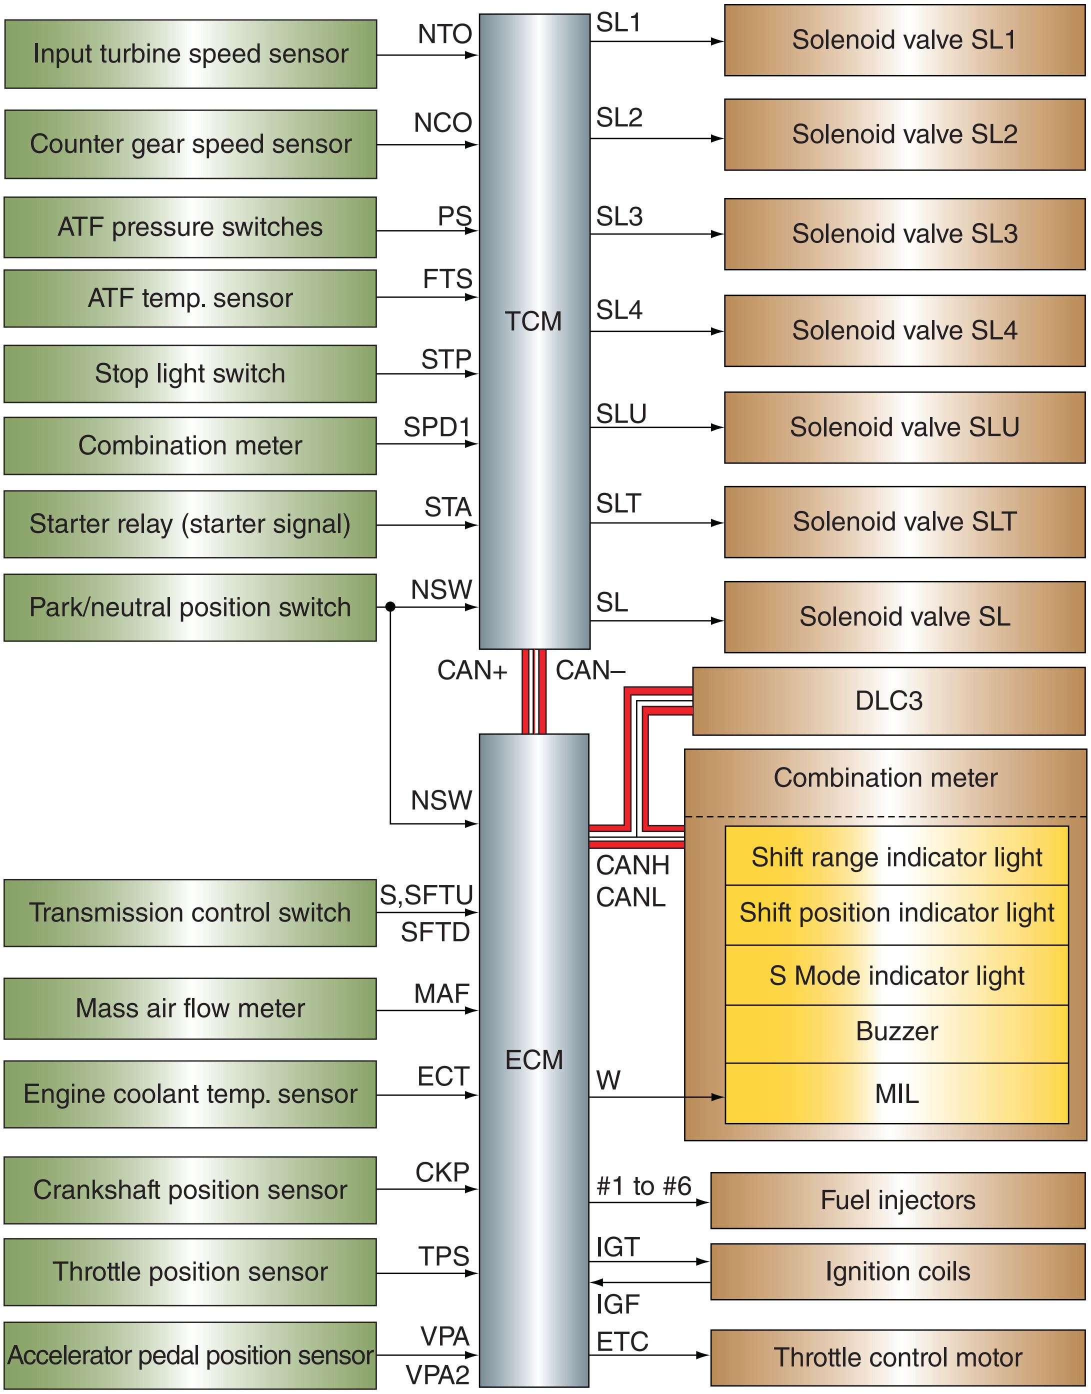

FIGURE 42–2 The different inputs, modules, and outputs in an EAT circuit.

module (BCM), or the powertrain control module (PCM). Some manufacturers mount the TCM on the valve body inside the transmission. Doing this reduces the number of required electrical connectors and the amount of wiring. The TCM is tied into the serial (CAN) bus and shares information with the PCM.

Transmission Control Module

A TCM is programmed to provide gear changes at the optimum time. The TCM controls shift timing, shift feel, and the operation of the torque converter clutch. To determine the best operating strategy for

the transmission, the TCM uses inputs from some engine-related and driver-controlled sensors. The TCM also receives input signals from specific sensors connected to the transmission. By monitoring all of these inputs, the TCM can determine when to shift gears or when to apply or release the torque converter clutch.

The decision to shift or not to shift is based on the shift schedules and logic. A **shift schedule** contains the actual shift points to be used by the computer according to the input data it receives from the sensors. Shift schedule logic chooses the appropriate gear and then determines the correct shift schedule or pattern that should be followed. Each possible engine/transmission combination for a vehicle has a different set of shift schedules. The shift schedules set the conditions required for a change in gears. The computer frequently reviews the input information and can make quick adjustments to the schedule, if needed and *as* needed. To control shift quality, the TCM works with the PCM to momentarily alter engine output. This is accomplished by changing the ignition timing during a shift. The reduction in engine torque during shifting allows for smooth gear changes.

The electronic control systems used by the manufacturers differ with the transmission models and the engines to which they are attached. The components in each system and their operation also vary with the different transmissions. However, all operate in a similar fashion and use basically the same parts.

Inputs

The computer may receive information from two different sources: directly from a sensor or through the CAN communication bus that connects all of the vehicle's computer systems **(Figure 42–3)**. Normal engine-related inputs are used by the TCM to determine the best shift points. Many of these inputs are available at the common data bus. Other information, such as engine and body identification, the TCM's target idle speed, and speed control operation are not the result of monitoring by sensors; rather, these have been calculated or determined by the TCM and made available on the bus.

Typical data inputs used by the TCM include:

- Accelerator pedal position (APP) and throttle position (TP)
- Engine load
- Engine speed
- Gear range or manual gear selection
- Vehicle speed
- Manifold absolute pressure (MAP)
- Mass airflow (MAF)
- Intake air temperature (IAT)
- Barometric pressure (BARO)
- Engine coolant temperature (ECT)
- ATF temperature
- Crankshaft position (CKP) sensors
- Line pressure
- Input shaft speed
- Intermediate speed
- Output shaft speed
- Brake application
- A/C on-off
- Cruise control on-off

These provide the TCM with information about the operating condition of the engine and transmission. Through these, the TCM is able to control shifting and torque converter clutch operation according to the temperature, speed, and load of the engine.

Inputs that are tied directly to the TCM are typically not available on the bus circuit. Many of these sensors produce an analog signal that must be changed to a digital signal before the TCM can respond. This conversion is handled by an analog-to-digital (A/D) converter, the PCM, or a digital radio adapter controller (DRAC). These typically convert an analog AC signal to a digital 5-volt square wave.

The TCM constantly monitors what is happening inside the transmission with various speed and gear range sensors that tell it if the gears are shifting correctly and at what speeds. Once the TCM commands a gear change, solenoids are energized to hydraulically control the engagement of the proper clutch or band.

On-Off Switches Several simple switches are used in the control of an EAT. The number and purpose of each depends on the system. A brake pedal position (BPP) switch tells the TCM when the brakes are applied. At that time, the torque converter clutch disengages. The BPP switch closes when the brakes are applied and opens when they are released. Its input has little to do with the up-and-down shifting of gears, except that in some systems it signals a need for engine braking.

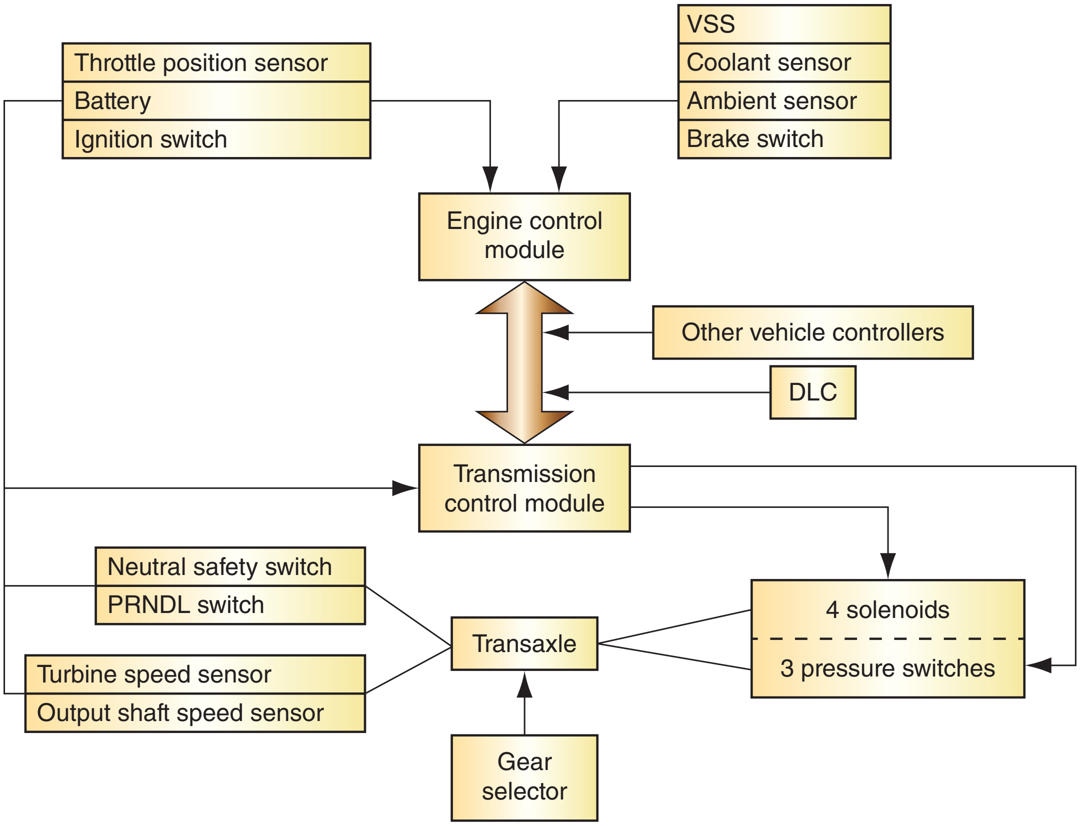

FIGURE 42–3 The electric circuit for a typical electronically controlled transmission. Note: The CCD data BUS is the data source for other inputs in this multiplexed circuit.

The transmission control (TC) switch is a momentary contact switch located on the selector lever that allows the driver to cancel operation of overdrive. When the TC switch is depressed, a signal is sent to the PCM to disengage overdrive operation. At the same time, the PCM illuminates the transmission control indicator lamp (TCIL) to notify the driver that overdrive is canceled.

An A/C request switch tells the TCM that the A/C has been turned on. The TCM then changes the line pressure and shift timing to accommodate the extra engine load created by the A/C system. When the A/C clutch is engaged, the electronic pressure control (EPC) is adjusted by the TCM to compensate for the additional load on the engine.

EATs also have cruise control input that informs the TCM when cruise control is active. In this mode, shift patterns are altered to reduce excessive and harsh shifting. There may also be a four-wheel drive low (4WDL) range switch that lets the TCM know when the four-wheel drive transfer case gear is in its low range.

Digital Transmission Range (TR) Sensor The first input that the TCM looks at is the position of the gear shift lever. All shift schedules are based on the gear selected by the driver. These schedules are coded by the position of the gear selector and the current gear range and use throttle angle and vehicle speed as primary determining factors. A digital transmission range (TR) sensor informs the TCM of the gear selected by the driver. This sensor may also contain the neutral safety switch and the reverse light switch. A TR sensor is typically a multiple-pole-type on-off switch **(Figure 42–4)**. The digital TR sensor may be located on the outside of the transmission at the manual lever or it may be internal or part of the TCM.

Accelerator Pedal Position (APP) and Throttle Position (TP) Sensors Depending on if the vehicle is drive by wire, either the APP or the TP sensor sends a voltage signal to the TCM in response to TP. Not only is this signal used to inform the TCM of the driver's intent, it is also used in place of the hydraulic throttle pressure linkage. The APP/TP sensor is very

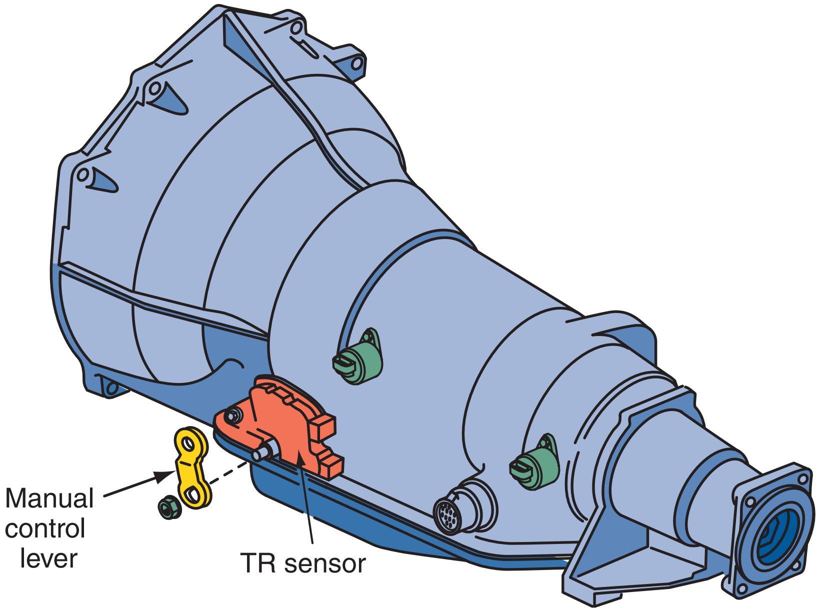

FIGURE 42-4 A TR sensor.

important to the operation of an EAT and is used for shift scheduling, EPC, and TCC control.

If the APP/TP signal is wrong, it can affect transmission kickdown shifts during acceleration as well as upshifts and downshifts. When the TCM is unable to get a good signal, it may substitute a "calculated" TP based on other inputs from the data bus. Regardless, the TCM always calculates a TP based on its programming and inputs. This calculation is one of the most important inputs for shift pattern logic. A very low APP/TP angle causes upshifts to occur early, and very high angles cause early downshifts.

Mass Airflow (MAF) Sensor The MAF sensor measures the mass of air flowing into the engine and is primarily used to calculate injector pulse width. It also is used to calculate engine load and to regulate electronic pressure control (EPC) and shift and TCC scheduling. Depending on the type of fuel injection system used (speed density or airflow), engine load may be determined by the TP sensor, MAP sensor, and/or a vane airflow VAF sensor or MAF sensor.

Signals from a BARO sensor are used to adjust line pressures according to changes in altitude. This sensor input may not be used; its use depends on the type of intake air monitoring system the vehicle is equipped with. On those vehicles using the BARO sensor as an input, the sensor may be integrated in the PCM or it may be mounted externally.

Engine Speed

To ensure that the transmission shifts at the correct time, the TCM must receive an engine speed input. This can be done through the ignition module or PCM and serial data bus or through a direct connection from a dedicated circuit between the CKP sensor and TCM. With the direct connection, all time delays at the bus circuit are eliminated and the TCM always knows the current engine speed. This input is used to determine shift timing, wide-open throttle (WOT) shift control, TCC control, and EPC pressure. Also, to prevent the engine from running at too high of a speed, the TCM will order an upshift.

Temperature Sensors Shift schedules are also influenced by the engine's temperature. Sometimes the engine's temperature is raised by delaying gear shifts. When the engine is overheating, shifts will occur sooner. The computer may also engage the converter clutch in second or third gear if the coolant temperature rises. Engine temperatures are often tied to ATF temperatures in the computer and are critical to the operation of a transmission.

The IAT sensor provides the fuel injection system with mixture temperature information. The IAT sensor is used both as a density corrector for airflow calculation and to proportion cold enrichment fuel flow. It is installed in the air cleaner outlet tube. The IAT sensor also is used in determining line pressures.

The TCM may also use the signal from the IAT to calculate the temperature of the battery. The TCM then uses this temperature to estimate transmission fluid temperature.

Transmission Fluid Temperature (TFT) Sensor The transmission fluid temperature (TFT) sensor is normally located on the valve body. Signals from the sensor tell the TCM what the temperature of the ATF is. The sensor is a thermistor whose output signal varies with ATF temperature. The TCM uses this signal to control shift timing, shift feel, and TCC engagement. When the signal indicates normal operating temperature, the transmission is shifted normally; however, when the fluid is too cold or too hot, shifting is altered.

When the fluid temperature is too high, the TCM will operate the transmission in a way to allow it to cool. Shifts will occur sooner than normal. When the fluid is too cold, shifting is delayed to help warm the fluid. Fluid temperature is used, along with other inputs, to control TCC clutch engagement. When the fluid is cold, the TCM prevents TCC engagement until the fluid reaches a specific temperature.

Some transmissions operate with distinct shift schedules based on fluid temperature. **Figure 42–5** shows the operating characteristics of a Chrysler 45RFE transmission when the ATF is at different temperatures.

If the TFT sensor fails or the TCM determines temperature signals are incorrect, the TCM will look at engine temperature to estimate the temperature of the ATF.

Transmission Pressure Switches Various transmission pressure switches **(Figure 42–6)** can be used to keep the TCM informed as to which hydraulic circuits are pressurized and which clutches and brakes are applied. These input signals can serve as verification to other inputs and as self-monitoring or feedback signals. The most commonly used pressure switch is the transmission fluid pressure (TFP) switch, which monitors fluid pressure to determine when a clutch or band is applied or released.

Voltage-Generating Sensors A variety of speed sensors, most commonly Hall-effect or PM generator sensors, are used in today's EATs. These sensors serve as the governor signal and monitor the operation of the transmission. Some TCMs receive a signal from a vehicle speed sensor (VSS) and use this to determine the correct time to shift. Some EATs have intermediate speed and an output shaft speed (OSS) sensors. These sensors may be used with the

VSS or provide a vehicle speed reference for the TCM. When a vehicle has both sensors, the OSS signal is used as a verification signal for the VSS, or vice versa. The OSS is typically used for control of torque converter clutch operation, shift timing, and fluid pressure control.

Many transmissions have an input speed sensor (ISS) or a turbine speed (TSS) sensor. This sensor is identical to the OSS and its signal is used to calculate converter turbine speed **(Figure 42–7)**. It is also used, along with an engine speed input, to determine the amount of T/C slip by providing the TCM with the difference between engine speed and transmission input shaft speed. This is used to determine the amount of pressure applied to the TCC. Comparing input, intermediate and output shaft rotation speeds also allows the TCM to determine if shifts are occurring properly, or if they are too quick or are taking too long **(Figure 42–8)**. Four-wheel drive vehicles may have an additional speed sensor in the transfer case.

Outputs

Common outputs used with EATs are indicator lamps and solenoids. The indicator lamps can show the selected gear range in the instrument panel. They may also be a MIL designated for the transmission, or this warning light may be incorporated into the

circuit for the engine's MIL. Shift, pressure control, and TCC solenoids are used in all modern EATs. All of these are controlled by the TCM. The solenoids are typically located inside the transmission and are mounted to the valve body.

Shift Solenoids Shift solenoids **(Figure 42–9A)** are used to regulate shift timing and feel by controlling the delivery of fluid to a manual shift valve or to a clutch pack. These solenoids are on-off solenoids that are normally off and in the open position. When open, line pressure is present at the manual or selected shift valve. When the shift solenoids are energized **(Figure 42–9B)**, they block line pressure and allow pressure to exhaust from around the shift valve. This allows the valve to move. Another way of controlling the shift valve is if the normally open solenoid is used to vent pressure from the shift valve **(Figure 42–10A)**. When commanded closed, pressure builds against the valve and it moves against the spring **(Figure 42–10B)**.

The number and purpose of each depends on the model of transmission. A typical four-speed unit has two shift solenoids. The two solenoids offer four possible on-off combinations to control fluid to the various shift valves. This provides the engagement of the four forward gears **(Figure 42–11)**. Transmissions with additional forward gears rely on additional shift solenoids. For example, the eight-speed 8L90 transmission from GM has five shift solenoids plus a boost solenoid. The on-off combinations of these provide the additional gears. It is important to note that the TCM will stop current flow to a shift solenoid if it detects a fault in the solenoid or its circuit.

Pressure Control Solenoids The pressure control solenoid replaces the conventional TV cable setup to provide changes in line pressure in response to

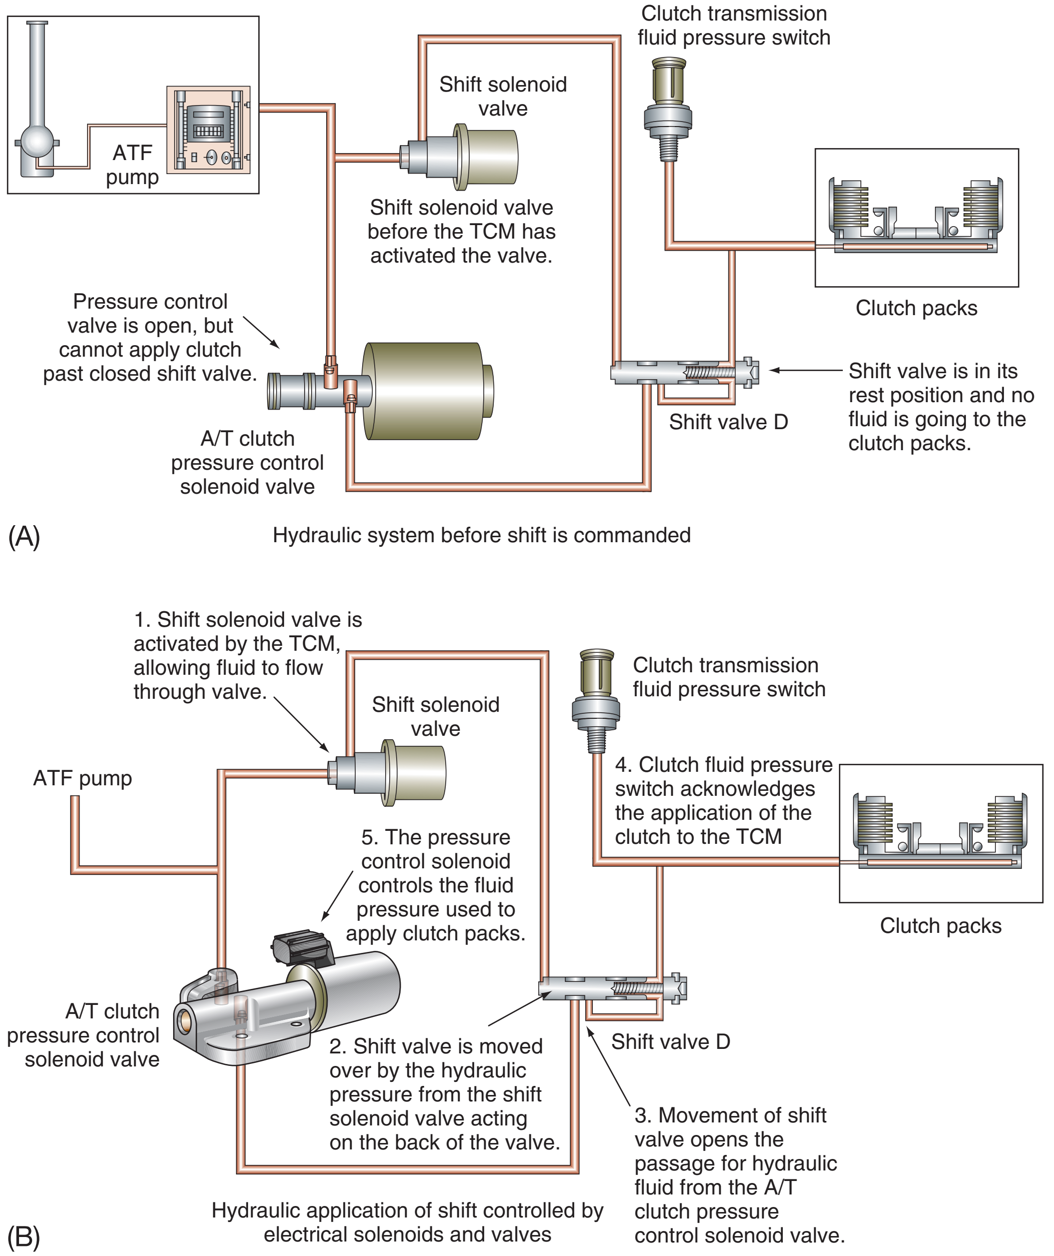

FIGURE 42–10 (A) Fluid flow blocked by the shift valve. (B) Pressure moving the shift valve and applying the clutch pack.

engine running conditions and engine load. The action of the solenoid controls the operating hydraulic pressures to the clutches and brakes to provide smooth and precise shifting. The pressure control solenoid is installed on the valve body.

In most cases, the pressure control solenoid is called an electronic pressure control (EPC) solenoid and is duty cycle controlled by the TCM. Most of these solenoids are **variable force solenoids (VFS)** or pulse width modulated (PWM) solenoids and contain a spool valve or plunger and a spring. To control fluid pressure, the PCM sends a varying signal to the solenoid. This changes the amount the solenoid will cause the spool valve to move. When the solenoid is off, spring tension keeps the valve in place to maintain maximum pressure. When the solenoid is energized it moves the spool valve. The movement of the valve uncovers the exhaust port around the valve, thereby causing a decrease in pressure **(Figure 42–12)**.

TCC Solenoid The TCC solenoid is used to control the application, modulation, and release of the TCC. The operation of the converter clutch is also totally controlled by the TCM. The exception to this is when

the clutch is hydraulically disabled to prevent engagement regardless of the commands from the computer. The converter clutch is hydraulically applied and electrically controlled through a PWM solenoid controlled by the TCM **(Figure 42–13)**. When the solenoid is off, TCC signal fluid exhausts and the converter clutch remains released. Once the solenoid is energized, TCC signal fluid passes to the TCC regulator valve and the clutch, engaging it. Modulating the pressure to the clutch allows for smooth engagement and disengagement and also allows for partial engagement of the clutch.

Whenever the TCM detects a problem in any of the solenoids in a transmission, it will disable the TCC solenoid.

Adaptive Controls

Most late-model EATs have systems that allow the TCM to change transmission behavior based on the current condition of the transmission and engine, current operating conditions, and the habits of the driver. When systems are capable of doing this, they have **adaptive learning** capabilities. Adaptive learning provides consistent quality shifting and increases the durability of the transmission.

These transmissions have a line pressure control system that compensates for the normal wear of a transmission. As parts wear or conditions change, the time required to apply a clutch or brake changes. The TCM monitors the input and output speeds of the transmission during commanded shifts to determine if a shift is occurring too fast (harsh) or too slow (soft) and adjusts the line pressure to maintain the desired shift feel. Adaptive learning takes place as the TCM reads input and output speeds more than 140 times per second.

The system may also monitor the condition of the engine and compensate for any changes in the engine's performance. It also monitors and memorizes the typical driving style of the driver and the operating conditions of the vehicle. With this information, the computer adjusts the timing of shifts and converter clutch engagement to provide good shifting at the appropriate time.

SHOP TALK

EATs with adaptive learning may display harsh and/or abrupt shifting when they are new. This is normal because the TCM has not yet received enough information to learn about the vehicle or driver. This shifting behavior may also occur after the vehicle's battery has been disconnected for a long period.

In addition, some transmissions have part unique numbers (PUN) and transmission unique numbers (TUN) that are used for programing and adaption. In the GM 8L90, each shift solenoid has a PUN that identify the performance characteristics of each solenoid. This information is stored in the TCM and is used for precise control of each solenoid. If the transmission, valve body, solenoids, or TCM require replacement, the data stored by the TCM must be downloaded and programmed into the replacement TCM for the transmission to function correctly.

Limp-In Mode

When the TCM detects a serious transmission problem or a problem in its circuit (or in some cases an engine control or data bus problem), it may switch to a default, limp-in, or fail-safe mode. Limp-in may also be initiated if the TCM loses its battery power feed. This mode allows for limited driving capabilities and is designed to prevent further transmission damage while allowing the driver to drive with decreased power and efficiency to a service facility for repairs.

The capabilities of a transmission while it is in limp-in mode depend on the extent of the fault, the manufacturer, and the model of transmission. When the TCM moves into the limp-in mode, a DTC is set and the transmission will only operate in this mode until the problem is corrected. Examples of operating characteristics during limp-in include:

- The transmission locks in third gear when the gear selector is in the drive position or second gear when it is in a lower position.
- The transmission will remain in whatever gear it was in but will shift into third or second gear and stay there as soon as the vehicle slows down.
- The transmission will only use first and third gears while in the drive position.
- The transmission will operate only in park, neutral, reverse, and second gears and will not upshift or downshift.

Operational Modes

With electronic controls, automatic transmissions can be programmed to operate in different modes. The desired mode is selected by the driver. The mode selection switch can be located on the center console or the instrument panel. Most transmissions with this feature have two selective modes, normally called "Normal" and "Sport." During the normal mode, the transmission operates according to the shift schedule and logic set for normal or regular operation. In the sport mode, the TCM uses different logic and shift schedules to provide for better acceleration and performance with heavy loads. Normally this means delaying upshifts.

If three modes are available, the third mode is called the "Auto" mode. The auto mode is a mixture between the normal and power modes. While in this mode, the TCM will control the shifts in a normal way. However, if the throttle is quickly opened, the shift pattern will switch to the power mode.

Some late-model vehicles have a "Tow/Haul" switch. This operating mode delays upshifts and increases operating pressures when the vehicle is operating with a heavy load. The mode also provides quicker downshifts during deceleration, which allows for more engine braking. The torque converter's lock-up clutch is applied sooner and in more gears than normal during acceleration. This helps to keep the temperature of the fluid in the torque converter down. Also, the clutch remains engaged for a longer period of time during deceleration to improve engine braking. In this mode, the transmission is able to shift into overdrive when the vehicle's load is overcome.

Manual Shifting

One of the features of electronically controlled transmissions is the availability of manual shift controls. Many late-model EATs use electronic shifters instead

FIGURE 42–14 An electronic shifter.

of mechanical linkages **(Figure 42–14)**, which provide the driver the ability to easily shift the transmission manually, but with the convenience of an automatic transmission. Unlike a manual transmission, though, the driver does not need to depress a clutch pedal nor is there a clutch assembly on the flywheel. The driver simply moves the gear selector, uses the paddle shifter, or hits a button and the transmission changes gears. If the driver does not change gears and engine speed is high, the transmission shifts on its own. If the driver elects to let the transmission shift automatically, a switch disconnects the manual control and the transmission operates automatically.

CVT Controls

The electronic control system for a typical CVT consists of a TCM, various sensors, linear solenoids, and an inhibitor solenoid. Pulley ratios are always controlled by the control system. Input from the various sensors determines which linear solenoid the TCM will activate. Activating the shift control solenoid changes the shift control valve pressure, causing the shift valve to move. This changes the pressure applied to the driven and drive pulleys, which change the effective pulley ratio. Activating the start clutch control solenoid moves the start clutch valve. This valve allows or disallows pressure to the start clutch assembly. When pressure is applied to the clutch, power is transmitted from the pulleys to the final drive gearset **(Figure 42–15)**.

The start clutch allows for smooth starting. Because this transaxle does not have a torque converter, the start clutch is designed to slip just enough to get the car moving without stalling or straining the engine. The slippage is controlled by the hydraulic pressure applied to the start clutch. To compensate for engine loads, the TCM monitors the engine's vacuum and compares it to the measured vacuum of the engine while the transaxle was in park or neutral.

The TCM controls the pulley ratios to reduce engine speed and maintain ideal engine temperatures during acceleration. If the car is continuously driven at full throttle acceleration, the TCM causes an increase in pulley ratio. This reduces engine speed and maintains normal engine temperature while not adversely affecting acceleration. After the car has been driven at a lower speed or not accelerated for a while, the TCM lowers the pulley ratio. When the gear selector is placed into reverse, the TCM sends a signal to the PCM. The PCM then turns off the car's air conditioning and causes a slight increase in engine speed.

Audi's stepless Multitronic CVT is based on what it refers to as a variator. The variator is made of vanadium-hardened steel that is encased in oil and offers more durability than belt-driven CVTs. A manual gear selection mode is available and six simulated gear ratios can be selected. In the automatic mode, Multitronic calculates the optimum gear ratio with the aid of a dynamic regulating program, according to engine load, the driver's preferences, and driving conditions.

Hybrid Transmissions

Perhaps the most complex EATs are those used in many hybrid vehicles. The transmissions are fitted with electric motors that not only help propel the vehicle, but also provide a constantly variable drive ratio. These CVTs do not rely on belts and pulleys; rather, it is the electric motors that change the drive gear ratios. It is important to note that some hybrid vehicles rely on conventional CVTs and manual or automatic transmissions. This section covers the common nontraditional hybrid transmissions.

GO TO Chapter 35 for explanations of common hybrid vehicle systems.

Honda IMA Hybrid Models

A modified version of an automatic, manual, or CVT transaxle is used in Honda IMA hybrid vehicles. The transaxle is more compact so that it can fit behind the electric motor mounted at the rear of the engine **(Figure 42–16)** and occupy the same amount of

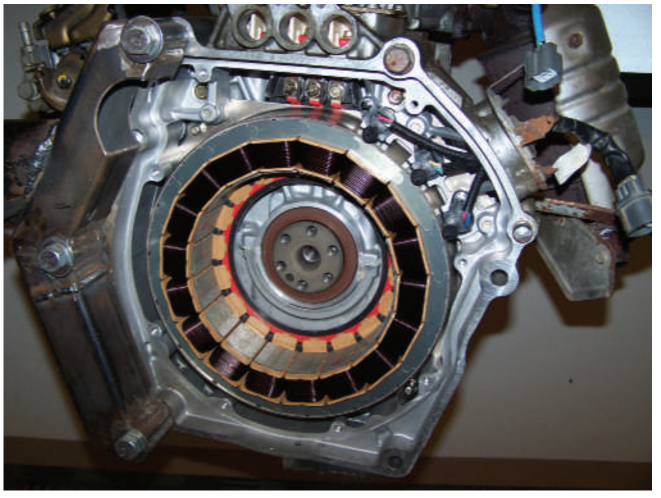

FIGURE 42–16 The IMA motor in Honda hybrids is mounted between the engine and transaxle.

space as the transaxle does in a nonhybrid vehicle. These transaxles operate in the same way as other Honda units. The automatic transaxle is fitted with an integrated electric oil pump and different gear ratios that provide for better acceleration, fuel economy, and regenerative braking.

Toyota and Lexus Hybrids

The power-split device used in Toyota and Lexus hybrids **(Figure 42–17)** operates as a continuously variable transaxle, although it does not use the belts and pulleys normally associated with CVTs. The variability of this transaxle depends on the action of a motor/generator, referred to as MG1, and the torque supplied by another motor/generator, referred to as MG2, and/or the engine.

This transaxle does not have a torque converter or clutch. Rather, a damper is used to cushion engine vibration and the power surges that result from the sudden engagement of power to the transaxle.

The engine and the two electric motors are connected to the planetary gearset. The gearset transfers power between the engine, MG1, MG2, and/or the drive wheels. The system splits power from the engine to different paths: to drive MG1 or drive the car's wheels, or both. MG2 can drive the wheels or be driven by them.

In the planetary gearset, the sun gear is attached to MG1. The ring gear is connected to MG2 and the final drive unit is in the transaxle. The planetary carrier is connected to the engine's output shaft **(Figure 42–18)**. The key to understanding how this system splits power is to realize that when there are two sources of input power, they rotate in the same direction but not at the same speed. Therefore, one can assist the rotation of the other, slow down the rotation of the other, or work together. Also, keep in mind that the rotational speed of MG2 largely depends on the power generated by MG1. Therefore, MG1 basically controls the continuously variable transmission function of the transaxle.

Ford Motor Company Hybrids

Ford's hybrids are equipped with an electronically controlled continuously variable transmission (eCVT). Based on a simple planetary gearset like Toyota's, however, Ford's transaxle is different in construction. In a Ford transaxle, the traction motor is not directly connected to the ring gear of the gearset. Rather, it is connected to the transfer gear assembly.

The effective gear ratios are determined by the speed of the motor/generator, engine, and traction motor. This means these determine the torque that

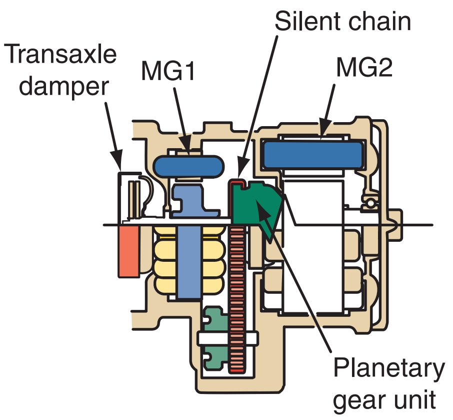

FIGURE 42–17 A typical power-split transaxle for a Toyota hybrid.

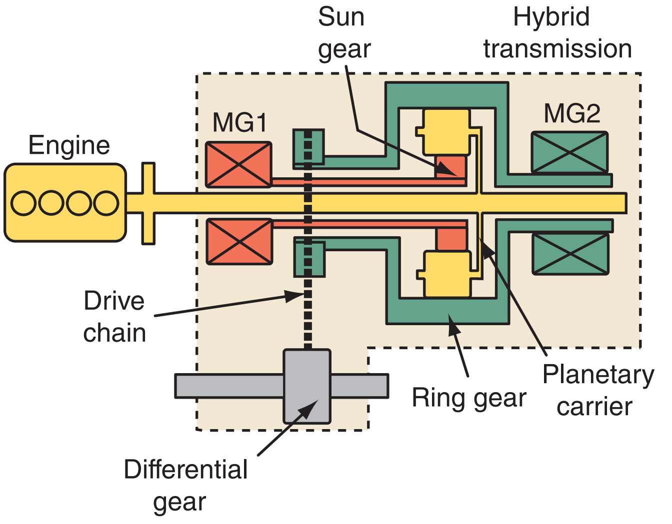

FIGURE 42–18 The arrangement of the electric motors and planetary gears in a power-split transaxle.

moves to the final drive unit in the transaxle. These power plants are controlled by the VSC through the TCM. Based on commands from the VSC and information from a variety of inputs, the TCM calculates the amount of torque required for the current operating conditions. A motor/generator control unit then sends commands to the inverter. The inverter, in turn, sends phased AC to the stator of the motors. The timing of the phased AC is critical to the operation of the motors as is the amount of voltage applied to each stator winding.

Two-Mode Transmissions

The two-mode full hybrid transmission relies on advanced hybrid, transmission, and electronic technologies to improve fuel economy and overall vehicle performance. It is claimed that the fuel consumption of a full-size truck or SUV is decreased by at least 25 percent when it is equipped with this hybrid system.

The system fits into a standard transmission housing and is basically three planetary gearsets coupled to two electronically controlled electric motors, which are powered by a 300-volt battery pack. This combination results in four forward speeds plus continuously variable gear ratios at low speeds and motor/generators for hybrid operation **(Figure 42–19)**.

Operation One motor is used to restart the engine after it shuts down at a traffic light or stop sign. It also assists the engine during low-speed acceleration. The other motor provides all propulsion power when reverse gear is selected and assists the engine during low speeds with a heavy load and when cruising at high speeds. During light-load operation up to 30 mph (48 km/h), the motor can propel the vehicle without the assistance of the engine. Both motors are used as generators to charge the battery pack when the vehicle is decelerating and braking.

The transmission uses clutch-to-clutch technology. The variable gear ratios are available through a mixing of power from the electric motors with the engine's power. When the motors are not providing power, the transmission operates like a conventional four-speed automatic.

The hybrid system has two distinct modes of operation. It operates in the first mode during low-speed and low-load conditions, and the second mode is used while cruising at highway speeds. The system can operate solely on electric or engine power or by a combination of the two. Typically, when one or both of the motors are not providing propulsion power, they are working as generators driven by the engine or by the drive wheels for regenerative braking.

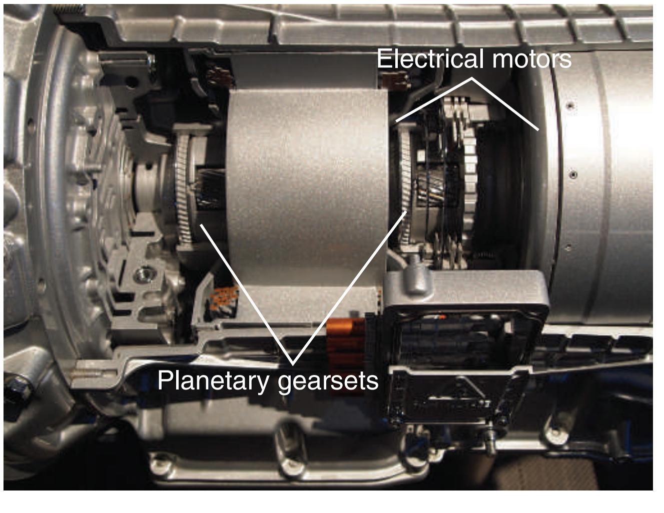

FIGURE 42-19 A planetary gearset is positioned in front of the two electric motors.

Basic EAT Testing

One of the first tasks during diagnosis of an EAT is to determine if the problem is caused by the transmission or by electronics. To determine this, the transmission must be observed to see if it responds to commands given by the computer. Identifying whether the problem is the transmission or electrical will determine what steps need to be followed to diagnose the cause of the problem.

EATs work only as well as the commands they receive from the computer, even if the hydraulic and mechanical parts of the transmission are fine. All diagnostics should begin with a scan tool to check for trouble codes in the system's computer. After the received codes are addressed, you can begin a more detailed diagnosis of the system and transmission. Your next step may be manually activating the shift solenoids by connecting a jumper wire to them or by using a transmission tester that allows you to manually activate the solenoids. Prior to doing this, study the wiring diagram for the solenoids to determine if the computer activates them by supplying voltage to them or by completing the ground circuit **(Figure 42–20)**. In addition, you need to know in which gear certain solenoids are activated.

The best way to diagnose an electronically controlled transmission is to approach solving the problem in a logical way.

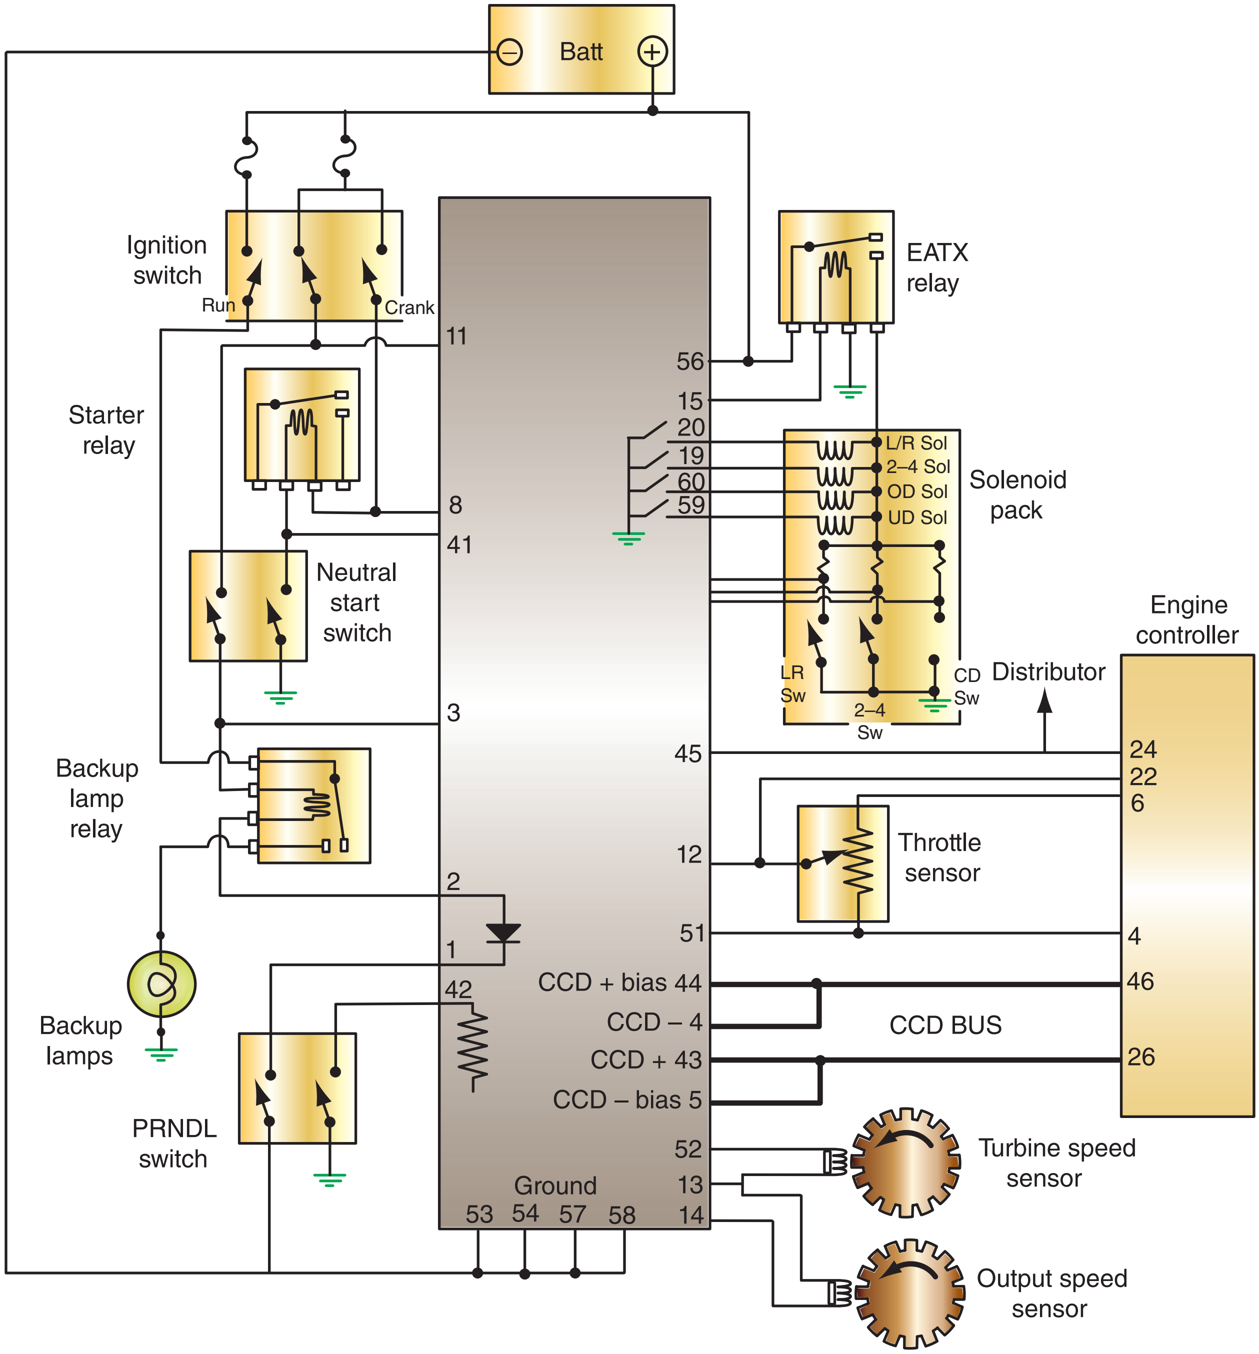

FIGURE 42–20 The electrical circuit for a typical EAT.

Because many EAT problems are caused by the basics, it is wise to conduct all of the preliminary checks required for a nonelectronically controlled transmission. Also, thoroughly inspect the electronic system. This inspection should include a check of the MIL and the retrieval of diagnostic codes. Doing this will also allow you to pull engine-related codes as well as transmission codes. Whenever diagnosing a transmission, remember that an engine problem can and will cause the transmission to act abnormally.

Scan Tool Checks

GO TO Chapter 25 for details on connecting a scan tool and retrieving DTCs.

Using a scan tool is one of the first steps of EAT diagnostics. Prior to retrieving the DTCs, pay attention to the MIL. The MIL is basically an engine malfunction light, but if the TCM detects a problem that

PROCEDURE

The recommended procedure for troubleshooting an EAT involves seven distinct steps that should be followed according to the following order:

STEP 1 Verify the customer's complaint. Pay attention to the conditions that exist when the problem occurs.

STEP 2 Check for any related symptoms, such as engine overheating, a lit MIL, and other driveability problems.

STEP 3 Conduct preliminary inspections and checks.

STEP 4 Check all service information for information that may apply to the complaint, including service bulletins, symptom charts, and recall notices.

STEP 5 Interpret and respond to all diagnostic codes.

STEP 6 Follow the diagnostic routines given by the manufacturer to define and isolate the cause of the problem.

STEP 7 Fix the problem and verify the repair.

may affect emissions, it will send a request over the data bus to the PCM to turn on the MIL lamp. Therefore, if the MIL is lit, the engine or transmission can have a problem. Remember, the MIL does not light after all DTCs are set; it only is lit when there is a fault that could affect emission levels.

When diagnosing an EAT, make sure there are no engine-related codes that could affect the operation of the transmission. If there is an engine problem, fix it before continuing with your diagnosis.

DTCs that relate to transmission faults can be caused by engine or transmission input and/or output devices. These codes may seem to indicate a problem with an input or output circuit but may actually be caused by an internal transmission problem. Remember, codes are set by out-of-range values. Therefore, when the TCM is receiving a too low or high input signal, the cause is not necessarily a bad sensor. The sensor can be fine and a mechanical or hydraulic transmission problem is causing the abnormal signals. Not only can internal transmission problems cause codes to be set, but so can basic electrical problems. Problems such as loose connections, broken wires, corrosion, and poor grounds will affect the signals.

If the TCM is unable to communicate with the PCM, there is a data bus problem. These problems will normally result in poor operation as well as the inability to retrieve DTCs from the TCM. The PCM constantly monitors the data bus and if it is unable to establish communication, it will order a data bus DTC.

Although the first steps in diagnosis include retrieving DTCs, there are problems that will not be evident by a code. These problems are solved with further testing, symptom charts, or pure logic. This logic must be based on an understanding of the transmission and its controls. It is possible to pinpoint the exact cause of a transmission problem: Monitor the serial data with a scan tool **(Figure 42–21)**. The serial data stream allows you to monitor system activity during operation. Comparing the observed values to the manufacturer's

USING SERVICE INFORMATION

At times, the manufacturer will make new software available that will correct common customer complaints. Normally, these are concerns that have no obvious physical or electronic cause. Flashing the TCM may take care of the concern. Always check the latest TSBs from the manufacturer when diagnosing a transmission concern.

specifications will greatly help in diagnostics. However, it is possible that the data displayed by a scan tool is not the actual value. Most computer systems will disregard inputs that are well out of range and rely on a default value held in its memory. These default values are hard to recognize and do little for diagnostics; this is why the use of basic electrical troubleshooting equipment, such as wiring diagrams, diagnostic charts, DMMs, lab scopes, and special transmission testers, to check the system is common.

Preliminary EAT Checks

Critical to proper diagnosis of EAT and TCC control systems is a road test. The road test should be conducted in the same way as one for a nonelectronic transmission except that a scan tool should also be connected to the circuit to monitor engine and transmission operation.

During the road test, the vehicle should be driven in the normal manner. Pay close attention to all gear changes. Also, the various computer inputs should be monitored and the readings recorded for future reference **(Figure 42–22)**. Some scan tools have the

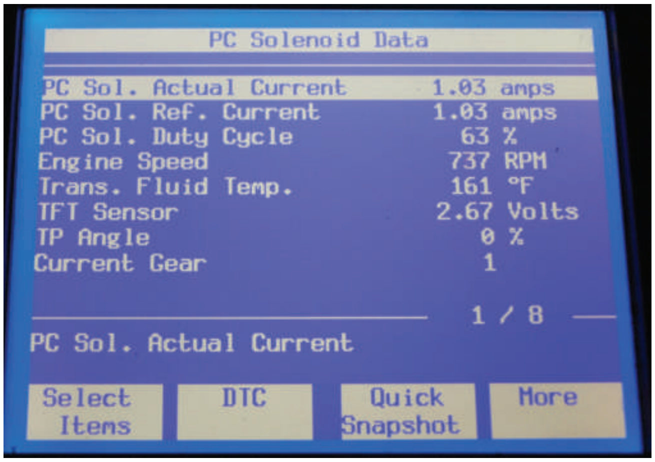

FIGURE 42–22 An example of some of the transmission-related data available on a scan tool.

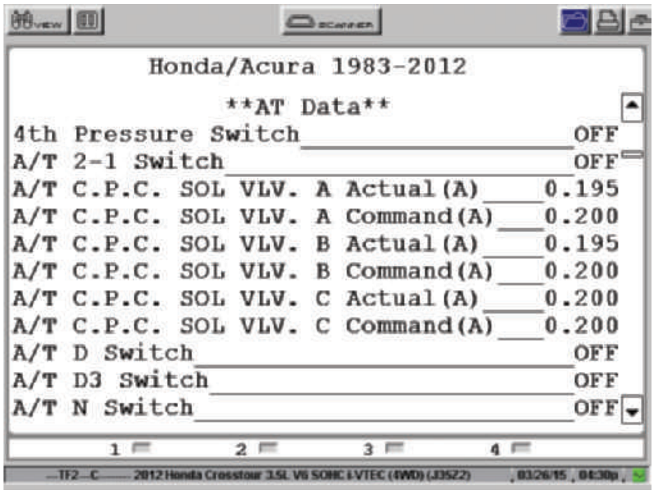

FIGURE 42–23 A display of other transmission specific data.

capability of printing out a report of the test drive. Critical information from the inputs includes engine speed, TP sensor, engine coolant, and transmission fluid temperatures **(Figure 42–23)** operating gear and the time it took to shift gears. If the scan tool does not have the ability to give a summary of the road test, you should record this same information after each gear or change in operating condition.

Often, accurately defining the problem and locating related information in TSBs and other materials can identify the cause of the problem. When a manufacturer recognizes common occurrences of a problem, a bulletin will be issued regarding the fix of the problem. Also, for many DTCs and symptoms, the manufacturers give a simple diagnostic chart or path for identifying the cause of the problem. These are designed to be followed step-by-step and will lead to a conclusion if you follow the path matched to the symptom. Check all available information before moving on in your diagnostics.

Sometimes the symptom will not match any of those described in the service information. This does not mean that it is time to guess; rather, it is time to clearly identify what is working right. By eliminating those circuits and components that are working correctly from a list of possible causes, you can identify what may be causing the problem and what should be tested further.

Common problems that affect shift timing and quality as well as the timing and quality of TCC engagement are incorrect battery voltage, a blown fuse, poor connections, a defective TP sensor or VSS, defective solenoids, crossed wires to the solenoids or sensors, corrosion at an electrical terminal, or faulty installation of an accessory.

Often computer-controlled transmissions will start off in the wrong gear. This can happen for

several reasons, such as either internal transmission problems or external control system problems. Internal transmission problems can be faulty solenoids or stuck valves. External problems can be the result of a complete loss of power or ground to the control circuit or the transmission is operating in its fail-safe mode. Typically, the default gear is simply the gear that is applied when the shift solenoids are off.

Electronic Defaults

While diagnosing a problem, always refer to the appropriate service information to identify the normal "default" operation of the transmission. You could spend time tracing the wrong problem by not recognizing that the transmission is operating in default.

Whenever the computer sees a potential problem that may increase wear and/or damage to the transmission, the system also defaults to limp-in mode. Minor slipping can be sensed by the computer through its input and output sensors. This slipping will cause premature wear and may cause the computer to move into its default mode; some systems may increase fluid pressure to compensate for the problem. A totally burnt clutch assembly will cause limp-in operation as will some internal pressure leaks that may not be apparent until pressure tests are run.

Guidelines for Diagnosing EATs

1. Make sure the battery has at least 12.6 volts before troubleshooting the transmission.
2. Check all fuses and identify the cause of any blown fuses.
3. Check the physical condition of all sensors and the wiring going to them **(Figure 42–24)**.

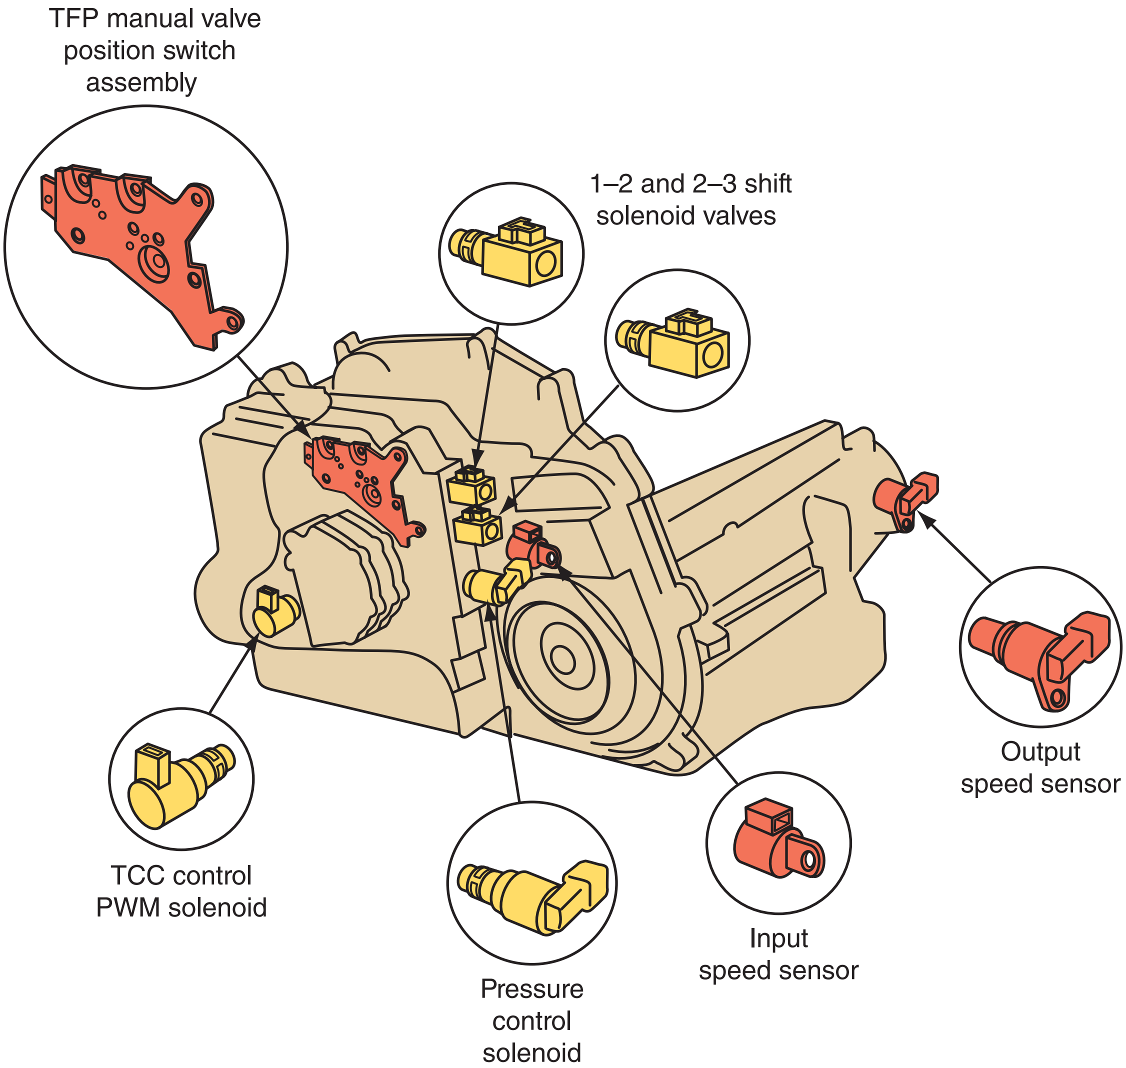

FIGURE 42–24 The typical location of the electronic components in or on a transaxle.

4. Compare the wiring to all suspected components with the wire colors given in the service information.
5. When testing electronic circuits, always use a high-impedance testlight or DMM.
6. If an output device is not working properly, check the power circuit to it.
7. If an input device is not sending the correct signal back to the computer, check the reference voltage it is receiving and the voltage it is sending back to the computer.
8. Compare the voltages in and out of a sensor with the voltages the computer is sending out and receiving.
9. Before replacing a computer, check the solenoid isolation diodes according to the procedures outlined in the service information.
10. Make sure the computer wiring harnesses do not run parallel with any high-current wires or harnesses. The magnetic field created by the high current may induce a voltage in the computer harness. Take necessary precautions to prevent the possibility of static discharge while working with electronic systems.
11. While checking individual components, always check the voltage drop of the ground circuits. This becomes more and more important as cars are made of less material that conducts electricity well.
12. Make sure the ignition is off when you disconnect or connect an electronic component.
13. Check all sensors in cold and hot conditions.
14. Check all wire terminals and connections for tightness and cleanliness.
15. Use a computer cleaning spray or comparable product to clean all connectors and terminals.
16. Use dielectric grease at all connections to prevent future corrosion.
17. If you must break through the insulation of a wire to take an electrical measurement, make sure you tightly tape over the area after you are finished testing.

Warning! Static electricity can destroy or render an electronic part useless. When handling any electronic part, do whatever is possible to reduce the chances of electrostatic buildup on your body and the inadvertent discharge to the electronic part.

Converter Clutch Control Diagnostics

To properly diagnose converter clutch problems, you must know when the TCC should engage and disengage and understand the function of the various controls involved with the system **(Figure 42–25)**. Although the actual controls for a TCC vary with the different models of transmissions, they all have certain operating conditions that must be met before the clutch can be engaged.

Diagnosis of a TCC circuit should be conducted in the same way as any other computer system. The computer will recognize problems within the system and store trouble codes that reflect the problem area of the circuit. A road test should be conducted to see if the problem is related to the TCC **(Figure 42–26)**.

On early electronically controlled systems with a TCC solenoid, the clutch is typically applied when oil flow through the torque converter is reversed. This change can be observed with a pressure gauge. Connect a pressure gauge to the fluid line from the transmission to the cooler. Position the gauge so that it is easily seen from the driver's seat. Then raise the vehicle on a hoist with the drive wheels off the ground and able to spin freely. Operate the vehicle until the transmission shifts into high gear. Then maintain a speed of approximately 55 mph (88 km/h). Once the speed is maintained, watch the pressure gauge.

If the pressure decreases 5 to 10 psi (0.35 to 0.70 kg/cm^2), the converter clutch was applied. With this action, you should feel the engagement of the clutch as well as a drop in engine speed. If the pressure changed but the clutch did not engage, the problem may be inside the converter or at the end of the input shaft. If the input shaft end is worn or the O-ring at the end is cut or worn, there will be pressure loss at the converter clutch. This loss in pressure will prevent full engagement of the clutch. If the pressure did not change and the clutch did not engage, suspect a faulty clutch valve or control solenoid or a fault in the solenoid control circuit.

If the clutch does not engage, check for power to the solenoid. If power is available, make sure the ground of the circuit is good. If there is power available and the ground is good, check the voltage drop across the solenoid. The solenoids should drop very close to source voltage. If less than that is measured, check the voltage drop across the power and ground sides of the circuit. If the voltage drop testing results are good, remove the solenoid and test it with an ohmmeter. Suspect clutch material, dirt, or other material plugging up the solenoid

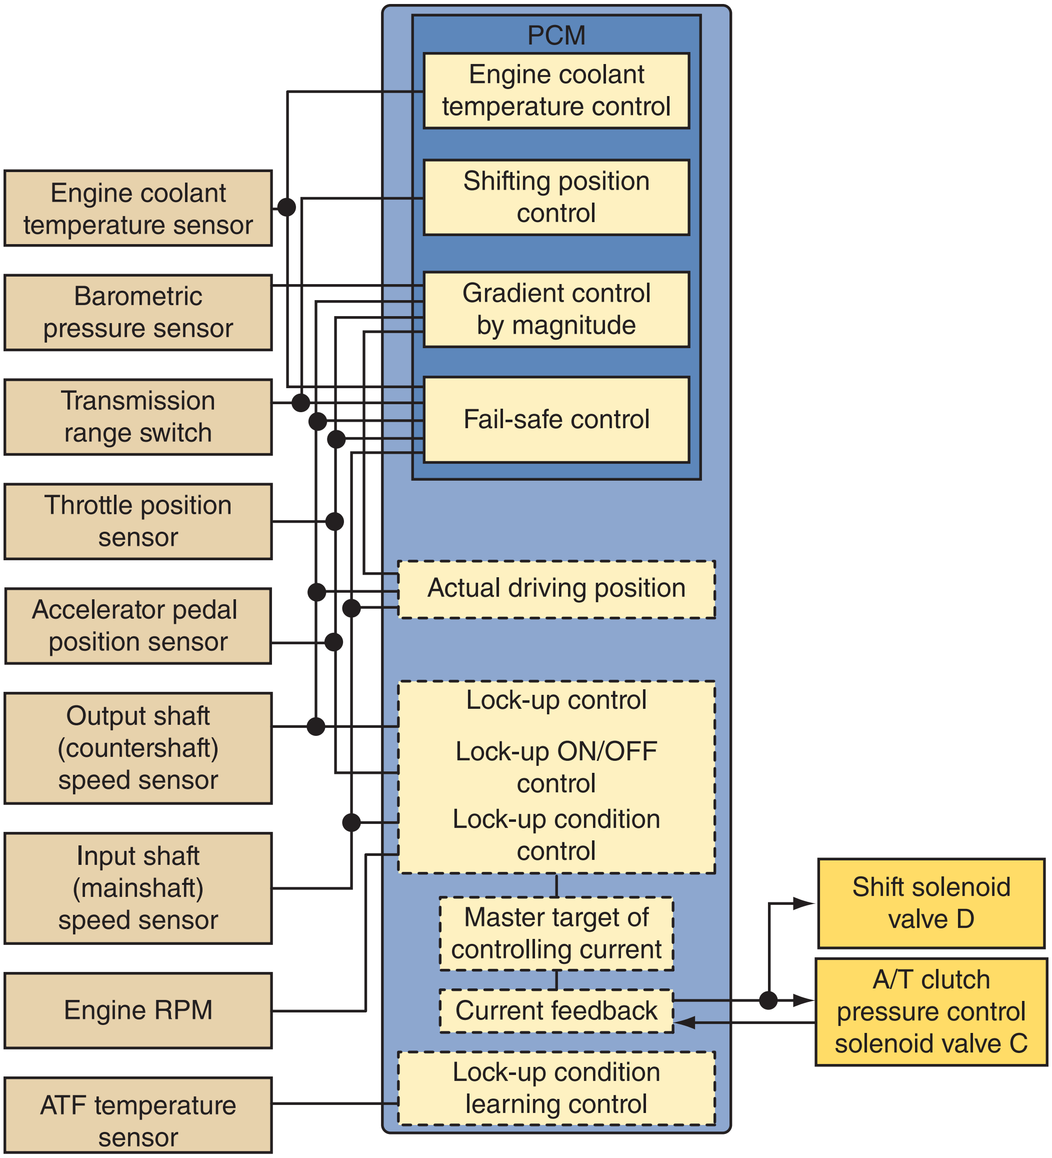

FIGURE 42-25 The electronic control system for a TCC.

valve passages if the solenoid checks out fine with the ohmmeter. Attempt to flush the valve with clean ATF if blockage is found. If the solenoid has a filter assembly, replace the filter after cleaning the fluid passages. Replace the solenoid if the blockage cannot be removed.

The TCC in late-model transmissions is controlled by the PCM or TCM. The computer turns on the converter clutch solenoid, which opens a valve and allows fluid pressure to engage the clutch. When the computer turns the solenoid off, the clutch disengages.

A malfunctioning converter clutch can cause a wide variety of driveability problems. Normally, the application of the clutch should feel like a smooth engagement into another gear. It should not feel harsh, nor should there be any noises related to the application of the clutch.

If the clutch engages at the wrong time, a sensor or switch in the circuit is probably the cause. If clutch engagement occurs at the wrong speed, check all speed-related sensors. A faulty temperature sensor may cause the clutch not to engage. If the sensor is not reading the correct temperature, the PCM may never realize that the temperature is suitable for engagement. Checking the appropriate sensors can be done with a scan tool, DMM, and/or lab scope.

Engagement Quality

If the clutch engages prematurely or is not applied with full pressure, a shudder or vibration results from the rapid grabbing and slipping of the clutch. This symptom can feel like an engine misfire or vibration. The clutch begins to engage then slips because it cannot hold the engine's torque. The torque

capacity of the clutch is determined by the oil pressure applied to it and the condition of the frictional surfaces of the clutch assembly.

If the shudder is only noticeable during the engagement of the clutch, the problem is typically in the converter. When the shudder is only evident after the engagement of the clutch, the cause of the shudder is the engine, transmission, or another component of the driveline. If the shudder is caused by the clutch, the converter must be replaced to correct the problem.

A faulty clutch solenoid or its return spring may cause low apply pressure. The valve controlled by the solenoid is normally held in position by a coil-type return spring. If the spring loses tension, the clutch will engage too soon. Because there is insufficient pressure to hold the clutch, shudder occurs as the clutch begins to grab and then slip. If the solenoid valve and/or return spring are faulty, they should be replaced, as should the torque converter. If the TCC fails to release, it can cause the engine to jerk and stall when the vehicle is stopping.

An out-of-round torque converter prevents full clutch engagement, which will also cause shudder, as will contaminated clutch frictional material. The frictional material can become contaminated by metal particles circulating through the torque converter and collecting on the clutch. Broken or worn clutch dampener springs will also cause shudder.

Detailed Testing of Inputs

There are many different designs of sensors that are part of the control system for an EAT. The transmission will not work properly if it receives bad information from its sensors or from the CAN bus. The transmission may shift at the wrong speeds, shift harshly, or operate only in the limp-in mode.

Some sensors are nothing more than a switch that completes a circuit. Others are complex devices that react to chemical reactions and generate their own voltage during certain conditions. If the preliminary tests pointed to a possible problem in an input circuit, the circuit should be tested. Make sure to check all suspect circuits for resistance problems; conduct voltage drop tests on those circuits. Often the manufacturers will give specific testing procedures for their sensors; always follow them.

GO TO Chapter 25 for details on specific tests of input devices.

Testing Switches

Many different switches are used as inputs or control devices for EATs. Most of the switches are either

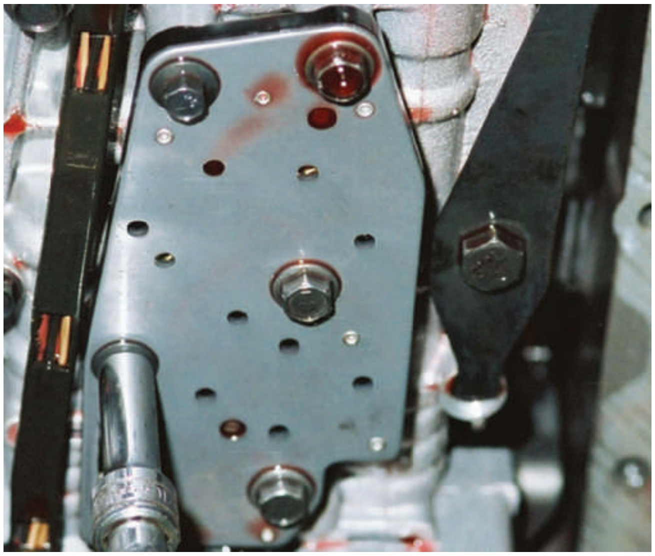

FIGURE 42–27 A typical transmission pressure switch assembly.

mechanically or hydraulically controlled. These switches can be easily checked with an ohmmeter. With the meter connected across the switch's leads, there should be continuity or low resistance when the switch is closed and there should be infinite resistance across the switch when it is open. A testlight can also be used. When the switch is closed, power should be present at both sides of the switch. When the switch is open, power should be present at only one side.

Pressure switches can be checked by applying air pressure to the part that would normally be exposed to fluid pressure **(Figure 42–27)**. When applying air pressure to these switches, check them for leaks. Although a malfunctioning electrical switch will probably not cause a shifting problem, it will if it leaks. If the switch leaks off the applied pressure in a hydraulic circuit to a holding device, the holding member may not be able to function properly. When possible, you should check pressure switches when they are installed and controlled by the vehicle.

Temperature Sensors

Temperature sensors can be checked with an ohmmeter. To do so, disconnect the sensor. In most cases, the sensor can be checked at room temperature **(Figure 42–28)**. Determine the temperature of the sensor and measure the resistance across it. Compare your reading to the chart of normal resistance for that temperature, which is given in the service information.

Thermistor activity can be monitored with a lab scope. Connect the scope across to the output of the thermistor or temperature sensor. Run the engine

Test connections	Specified value

E2 - ground	156kΩ or higher

and watch the waveform. As the temperature increases, there should be a smooth increase or decrease in voltage. Look for glitches in the signal. These can be caused by changes in resistance or an intermittent open.

Speed Sensors

Speed sensors negate the need for hydraulic signals from a governor. When this sensor fails or sends faulty readings, it can cause complaints similar to those caused by a bad TP sensor. The most common complaints are no overdrive, no converter clutch engagement, and no upshifts.

The operation of a PM generator-type speed sensor can be tested with a DMM set to measure AC voltage. Raise the vehicle on a lift. Allow the wheels to be suspended so they can rotate freely. Connect the meter to the speed sensor. Start the engine and put the transmission in gear. Slowly increase the engine's speed until the vehicle is at approximately 20 mph, and then measure the voltage at the speed sensor. Slowly increase the engine's speed and observe the voltmeter. The voltage should increase smoothly and precisely with an increase in speed.

Magnetic pulse generator speed sensors can be tested with a lab scope. Connect the lab scope's

leads across the sensor's terminals. The expected pattern is an AC signal, which should be a perfect sine wave when the speed is constant. When the speed is changing, the AC signal should change in amplitude and frequency. If the readings are not steady and do not smoothly change with speed, suspect a faulty connector, wiring harness, or sensor.

A speed sensor can also be tested when it is out of the vehicle. Connect an ohmmeter across the sensor's terminals. The desired resistance readings across the sensor will vary with every individual sensor; however, you should expect to have continuity across the leads. If there is no continuity, the sensor is open and should be replaced. Reposition the leads of the meter so that one lead is on the sensor's case and the other to a terminal. There should be no continuity in this position. If there is any measurable amount of resistance, the sensor is shorted.

Detailed Testing of Actuators

If you were unable to identify the cause of a transmission problem through the previous checks, you should continue your diagnostics with testing the solenoids. This will allow you to determine if the shifting problem is the solenoids or their control circuit, or if it is a hydraulic or mechanical problem.

GO TO Chapter 25 for details on specific tests of output devices, including solenoids.

Before continuing, however, you must first determine if the solenoids are case grounded and fed voltage by the computer, or if they always have power applied to them and the computer merely supplies the ground. While looking in the service information to find this, also find the section that tells you which solenoids are on and which are off for each of the different gears.

To begin this test you should collect the tools and/or equipment necessary to manually activate the solenoids. Switch panels that connect into the solenoid assembly are available and allow the technician to switch gears by depressing or flicking a switch.

With the tester, the solenoids will be energized in the correct pattern and observe the action of the solenoids. To totally test the transmission, you should shift gears under light, half, and full throttle. If the transmission shifts fine with the movement of the switches, you know that the transmission is fine. Any shifting problem must therefore be caused by something electrical. If the transmission did not respond to the switch movements, the problem is probably in the transmission.

SHOP TALK

This type of tester is easily made. Get a wiring harness for the transmission you want to test. Connect the harness to simple switches. Follow the solenoid/gear pattern when doing this. To change gears, all you will need to do is turn off one switch and turn on the next.

At times, a solenoid will work fine during light throttle operation but may not allow the valve to exhaust enough fluid when pressure increases. To verify that the valve is not exhausting, activate the solenoid and then increase engine speed while pulling on the throttle cable. If the valve cannot exhaust, the transmission will downshift. Restricted solenoids are a common cause of rough shifting under heavy loads or full throttle but good shifting under light throttle.

Testing Actuators with a Lab Scope

You will be able to watch the actuator's electrical activity by observing its action on a lab scope. Normally, if there is a mechanical fault, this will affect its electrical activity as well. Some actuators are controlled by pulse width modulated signals **(Figure 42–29)**. These devices are controlled by varying the pulse width, signal frequency, and/or voltage levels. By watching the control signal, you can see the turning on and off of the solenoid **(Figure 42–30)**. All waveforms should be checked for amplitude, time, and shape. You should also observe changes to the pulse width as operating conditions change. A bad waveform will have noise, glitches, or rounded corners. You should be able to see evidence that the actuator immediately turns off and on according to the commands of the computer.

Testing Actuators with an Ohmmeter

Solenoids can be checked for circuit resistance and shorts to ground. This can typically be done without removing the oil pan. The test can be conducted at the transmission case connector. Individual solenoids can be checked with an ohmmeter by identifying the proper pins in the connector. Remember, lower-than-normal resistance indicates a short, whereas higher-than-normal resistance indicates a problem of high resistance. If you get an infinite reading across the solenoid, the solenoid windings are open. The ohmmeter can also be used to check

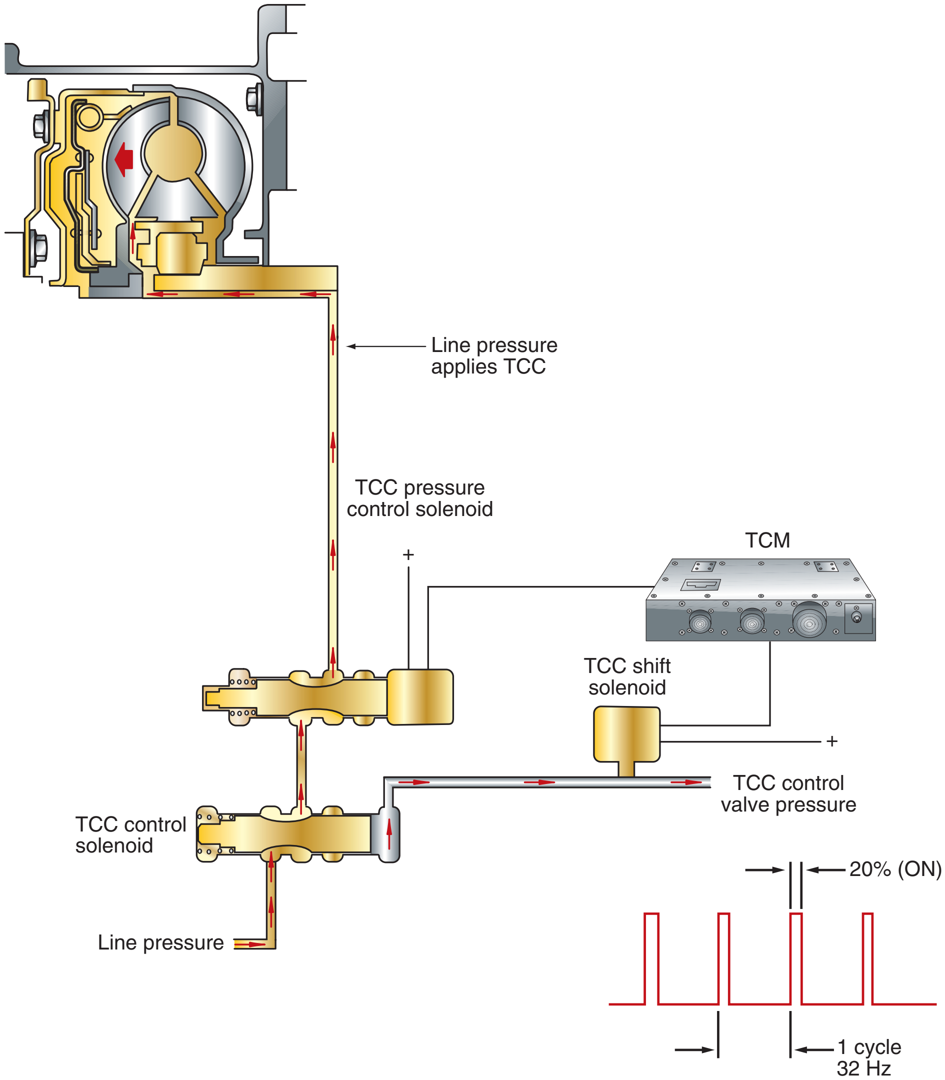

FIGURE 42–29 A typical control signal for a pulse width modulated solenoid.

for shorts to ground. Simply connect one lead of the ohmmeter to one end of the solenoid windings and the other lead to ground **(Figure 42–31)**. The reading should be infinite. If there is any measurable resistance, the winding is shorted to ground.

FIGURE 42–32 The appropriate service information lists the resistance values and test points for various transmission solenoids and sensors.

Solenoids can also be tested on a bench. Resistance values are typically given in service information for each application **(Figure 42–32)**. A solenoid may be electrically fine but still may fail mechanically or hydraulically. A solenoid's check valve may fail to seat or its porting can be plugged. This is not an electrical problem; rather, it could be caused by the magnetic field collecting metal particles in the ATF and clogging the port or check valve. These would cause erratic shifting, no shift conditions, wrong gear starts, no limited passing (kickdown) gear, or binding shifts. When a solenoid affected in this way is activated, it will make a slow, dull thud. A good solenoid tends to snap when activated.

Caution! When servicing the transmission of a Honda IMA hybrid, be careful of the high-voltage motor that is sandwiched between the engine and the transmission. Always disconnect the high voltage before working on or near the transmission.

SUMMARY

- A TCM is a separate computer designated for transmission operation or is part of the PCM. The PCM can be a multifunction computer that controls all engine and transmission operations.
- A shift schedule contains the actual shift points to be used by the computer according to the input data it receives from the sensors. Its logic chooses the proper shift schedule for the current conditions of the transmission.
- In most electronically controlled transmission systems, the hydraulically operated clutches are controlled by the transaxle controller.
- The typical output devices are solenoids and motors, which cause something mechanical or hydraulic to change.
- The computer may receive information from two different sources: directly from a sensor or through a twisted-pair bus circuit, which connects all of the vehicle computer systems.
- Fluid flow to the apply devices is directly controlled by the solenoids.
- Pressure switches give input to the transmission computer; they are all located within the solenoid assembly.
- Normally, the shift solenoids receive voltage through the ignition switch and are grounded through the PCM.
- The TCM is programmed to adjust its operating parameters in response to changes within the system, such as component wear. As component wear and shift overlap times increase, the TCM adjusts the line pressure to maintain proper shift timing calibrations. This is called adaptive learning.
- The pulse width modulated solenoid is a normally closed valve installed in the valve body. It controls the position of the TCC apply valve.
- If the TCM loses source voltage, the transmission will enter limp-in mode. The transmission will also enter into default if the computer senses a transmission failure. While in the default mode, the transmission will operate only in park, neutral, reverse, and one forward gear. This allows the vehicle to be operated, although its efficiency and performance are hurt.
- The basic shift logic of the computer allows the releasing apply device to slip slightly during the engagement of the engaging apply device.
- The EPC solenoid provides changes in pressure in response to engine load.
- Toyota, Ford, and Nissan hybrid systems rely on electric motors to determine the overall gear ratio in their CVTs.
- The two-mode hybrid system fits into a standard automatic transmission housing and is comprised of two planetary gearsets coupled to two electric motor/generators. This arrangement allows for two distinct modes of hybrid drive operation.
- If a computer's input signals are correct and its output signals are incorrect, the computer must be replaced.
- Input devices are critical to the operation of an EAT and should be checked with a scan tool, DMM, or lab scope.
- Solenoid valves can be checked by measuring their resistance or by applying a current to it and listening and feeling for its movement. They can also be checked with a lab scope or DMM.

AUTOMATIC TRANSMISSION AND TRANSAXLE SERVICE

OBJECTIVES

- Diagnose unusual fluid usage, level, and condition problems.
- Replace automatic transmission fluid and filters.
- Diagnose noise and vibration problems.
- Diagnose hydraulic control systems.
- Perform oil pressure tests and determine needed repairs.
- Inspect and adjust external linkages.
- Describe the basic steps for overhauling a transmission.

Because of the many similarities between a transmission and a transaxle, most diagnostic and service procedures are similar. Therefore, all references to a transmission apply equally to a transaxle unless otherwise noted. Whenever you are diagnosing or repairing a transaxle or transmission, make sure you refer first to the appropriate service information before you begin.

Transmissions are strong and typically trouble-free units that require little maintenance. Normal maintenance usually includes fluid checks, scheduled linkage adjustments, and oil and filter changes.

Identification

Always make sure you know exactly which transmission you are working on. This ensures you are following the correct procedures and specifications and are installing the correct parts. Proper identification can be difficult because transmissions cannot be

accurately identified by the way they look. The only exception to this is the shape of the oil pan, which can sometimes be used for identification. However, this is not foolproof.

The only positive way to identify a transmission is by its identification numbers. Transmission identification numbers are found on stickers on the transmission, stamped numbers in the case, or on a metal tag held by a bolt **(Figure 43–1)**. Also, all vehicles have a vehicle certification label that gives transmission information in a space marked TR. Use the service information to decipher the identification number. Most identification numbers include the model, manufacturer, and build date. Most late-model transmissions have labels with bar codes that can be scanned for transmission identification.

Basic Service

GO TO Chapter 8 for additional details on checking the fluid level in an automatic transmission.

For most transmissions, the fluid level and condition should be checked on a regular basis. Checking the fluid is also one of the initial steps to take while diagnosing a transmission concern.

When checking the fluid level, make sure the vehicle is on a level surface. Check the level and condition of the fluid. If the transmission has a dipstick, locate it **(Figure 43–2)**, remove it and wipe all dirt off the protective disc and the dipstick handle.

On most automobiles, the ATF level can be checked accurately only when the transmission is at operating temperature, the transmission is in a specific gear, and the engine is running. It is important to determine the correct operating temperature and conditions to get an accurate fluid check. Fluid temperature specs can range from less than 100° F (37.7° C) to nearly 200° F (93.3° C). According to one manufacturer, under-or overfilling by as little as a half a quart (473 mL) can cause shifting concerns. Remove the dipstick and wipe it clean with a lint-free white cloth or paper towel. Reinsert the dipstick, remove it again, and note the reading. Markings on a dipstick indicate ADD levels and on some models indicate FULL levels for cool, warm, or hot fluid.

Low fluid levels can cause a variety of problems. Air can be drawn into the oil pump's inlet circuit and mix with the fluid. This will result in aerated fluid, which causes slow pressure buildup, and low pressures, which cause slippage between shifts. Air in the pressure regulator valve will cause a buzzing noise when the valve tries to regulate pump pressure. If the fluid level is low, the problem could be external fluid leaks. Check the transmission case, oil pan, and cooler lines for signs of leaks.

Excessively high fluid levels can also cause **aeration**. As the planetary gears rotate in high fluid levels, air can be forced into the fluid. Aerated fluid can foam, overheat, and oxidize. All of these problems can interfere with normal valve, clutch, and servo operation. Foaming may be evident by fluid leakage from the transmission's vent.

FIGURE 43–3 Examples of the different fluid used in today's transmissions.

Examine the fluid carefully. The normal color of ATF is red. If the fluid has a dark brownish or blackish color and/or a burned odor, the fluid has been overheated. A milky color indicates that engine coolant has been leaking into the transmission's cooler in the radiator. If there is any question about the condition of the fluid, drain out a sample for closer inspection. If fluid needs to be added to the transmission, make sure it is the type recommended by the manufacturer **(Figure 43–3)**. Before adding fluid, check for any TSBs regarding updated fluid specifications. Although not very common, sometimes a manufacturer will make a change in the type of fluid that should be used.

Synthetic ATF is normally a darker red than petroleum- based fluid. Synthetic fluids tend to look and smell burnt after normal use; therefore, the appearance and smell of these fluids is not a good indicator of the fluid's condition.

After checking the ATF level and color, wipe the dipstick on absorbent white paper and look at the stain left by the fluid. Dark particles are normally band and/or clutch material, whereas silvery metal particles are normally caused by the wearing of the transmission's metal parts. If the dipstick cannot be wiped clean, it is probably covered with varnish, which results from fluid oxidation. Varnish will cause the spool valves to stick, causing shifting malfunction. Varnish or other heavy deposits indicate the need to change the transmission's fluid and filter.

Contaminated fluid can sometimes be felt better than be seen. Place a few drops of fluid between two fingers and rub them together. If the fluid feels dirty or gritty, it is contaminated with burned friction material.

Transmissions without a Dipstick Many late-model transmissions do not have a dipstick, and the fluid level is checked in a way similar to a manual transmission. Photo Sequence 37 covers the typical procedure for checking the transmission fluid level on transmissions without a dipstick. The dipstick and filler tube were removed from these transmissions to prevent overfilling. Research has found that many transmission failures were caused by overfilling and/or using the wrong fluid. Without a dipstick, it is difficult to check the fluid level and condition. These transmissions have a vent/fill cap typically located on the side of the transmission. Some also have a drain plug in the bottom of the pan. In addition, these transmissions are fitted with a fluid level sensor that will inform the driver when the fluid level is dangerously low.

Fluid Changes

The transmission's fluid and filter should be changed whenever there is an indication of oxidation or contamination. Periodic fluid and filter changes, as well as fluid flushes are part of the preventive program for most vehicles. The mileage interval recommended depends on the type of transmission.

Change the fluid only when the transmission is at normal operating temperatures. Photo Sequence 38 shows a typical procedure for changing a transmission's fluid and filter. On most transmissions, you must remove the oil pan to drain the fluid. A filter or screen is normally attached to the bottom of the valve body. Filters are made of paper or fabric and held in place by screws, clips, or bolts, or by the pressure on the pickup tube seal **(Figure 43–4)**. Filters should be replaced, not cleaned.

Some transmissions do not have a filter in the pan. Rather, they are fitted with a spin-on filter **(Figure 43–5)**. This filter looks like an engine filter. They are serviced in the same way as an engine oil filter. Some transmissions have both types of filters and both are serviced at the same time. Other transmissions may have an inline filter in the fluid lines leading to the cooler **(Figure 43–6)**.

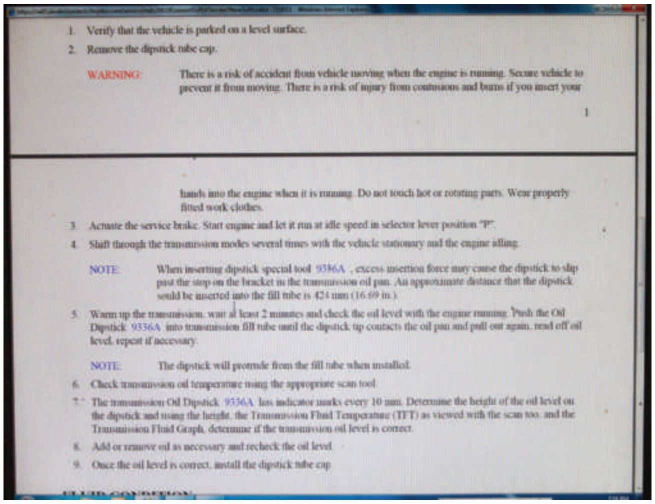
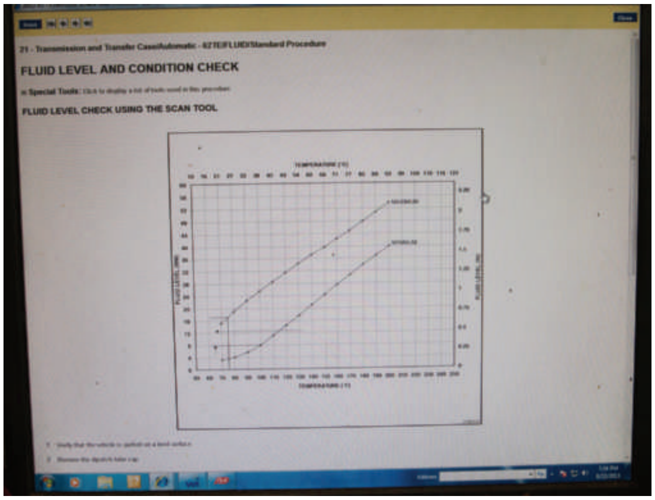
Make sure you always install the correct fluid in a transmission. Often the manufacturer recommends a special fluid for special applications. This is especially true of CVTs. Not only can the wrong fluid result in poor shifting; it can damage the transmission.

Checking Transmission Fluid Level on a Vehicle without a Dipstick

P37-1 Examine the transmission and determine how the fluid level is checked. If there is not a dipstick, often a service tag will indicate that special procedures are required.

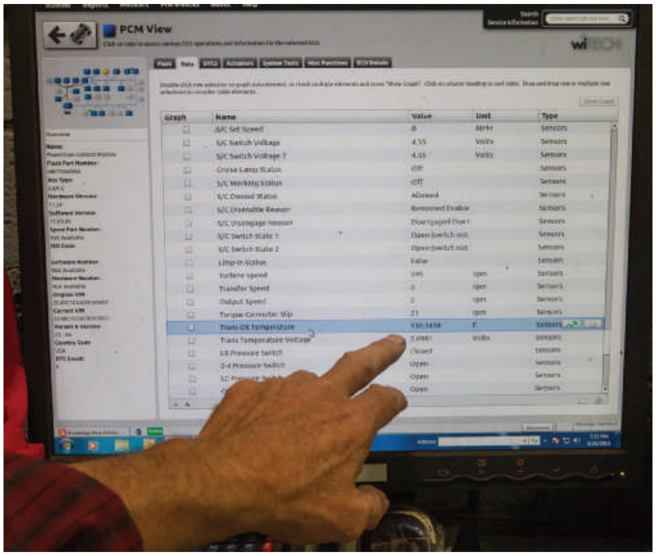


P37-2 Using the service information, determine how to check the transmission fluid level.



P37-3 Many vehicles require that the fluid level be checked with the fluid within a specific temperature range. This is to ensure that the fluid level is accurately determined as the fluid level reading changes as the fluid heats up.

P37-4 For this vehicle, a scan tool and a transmission fluid level tool are required to accurately determine the fluid level.



P37-5 To check transmission fluid temperature, connect a scan tool and locate the transmission fluid temperature PID. Once the fluid is within the correct range, continue with checking the fluid level.

P37-9 Using the temperature range chart, the fluid level as measured at 128° F (52° C) indicates the fluid level is acceptable.

FIGURE 43–4 Transmission fluid filters are attached to the transmission case by screws, bolts, retaining clips, and/or by the pickup tube.

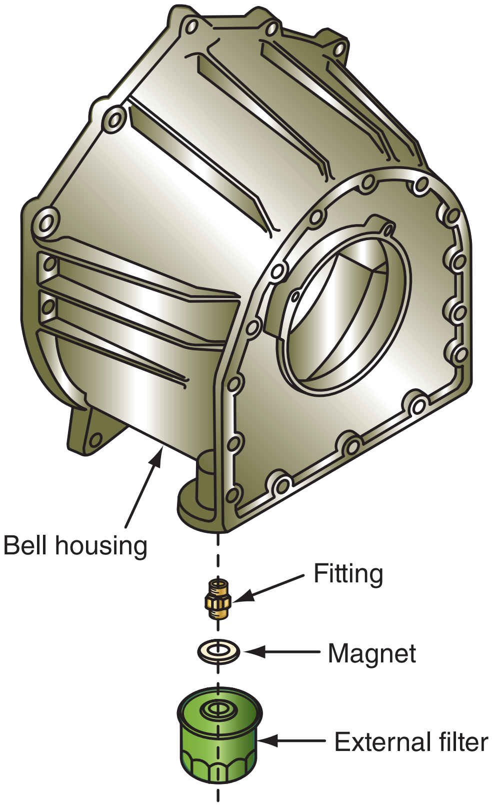

FIGURE 43–5 An engine oil filter-style transmission filter.

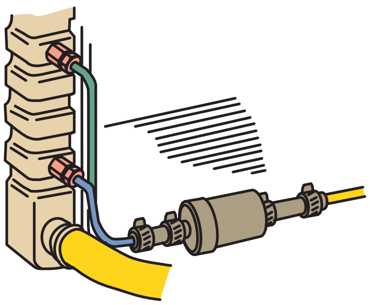

FIGURE 43–6 An inline filter for a fluid cooler.

Check the bottom of the pan for deposits and metal particles. Slight contamination, such as blackish deposits from clutches and bands, is normal. Other contaminants should be of concern. Clean the oil pan and its magnet **(Figure 43–7)**.

Remove the filter and inspect it. Use a magnet to determine if metal particles are steel or aluminum. Steel particles will be attracted to the magnet and indicate severe internal transmission wear or damage. If the metal particles are aluminum, they may be part of the torque converter stator. Some torque converters use phenolic plastic stators; therefore, aluminum particles found in these transmissions must be from the transmission itself.

Remove any traces of the old pan gasket on the case and oil pan. Then install a new filter and gasket and tighten the retaining bolts to the specified torque. If the filter is sealed with an O-ring, make sure it is properly installed. Reinstall the pan using the gasket or sealant recommended by the manufacturer. Tighten the bolts to the specified torque. The required torque is often given in inch-pounds. You can easily break the bolts or damage something if you tighten the bolts to foot-pounds.

Pour a little less than the required amount of fluid into the transmission through the filler tube or fill point. Start the engine and allow it to idle for at least 1 minute. Then, with the parking and service brakes applied, move the gear selector lever momentarily to each position, ending in park. Recheck the fluid level and add a sufficient amount of fluid to bring the level to about 1/8th inch below the FULL or MAX mark.

Bring the transmission up to normal operating temperature. Then recheck the fluid level and correct it if necessary. Make sure the dipstick is fully seated into the dipstick tube opening. This will prevent dirt from entering the transmission.

Parking Pawl

Any time you have the oil pan off, you should inspect all of the exposed parts, especially the parking pawl

SHOP TALK

Always check the service information for the correct conditions for checking fluid level. Although most manufacturers recommend checking it with the gear selector in the park position, some must be checked with the selector in neutral. In those transmissions, the fluid does not flow to the cooler when the transmission is in park.

P38-2 Place a large-diameter oil drain pan under the transmission pan.

P38-3 Loosen all of the pan bolts except three at one end. This will allow some fluid to drain out.

P38-4 Support the pan with one hand and remove the remaining bolts to remove the pan. Pour the fluid in the pan into the drain pan.

P38-5 Inspect the residue in the pan for indications of transmission problems. Then remove the old pan gasket and wipe the pan clean with a lint-free rag.

P38-6 Unbolt the filter from the transmission.

P38-7 Compare the replacement gasket and filter with the old ones to make sure the replacements are the right ones for this application.

P38-8 Install the new filter and tighten the attaching bolts to specifications. Then lay the new gasket over the sealing surface of the pan.

P38-9 Install the pan onto the transmission. Install and tighten the bolts to specifications. Then lower the vehicle and pour new fluid into the transmission. Run the engine to circulate the new fluid, then turn it off and raise the vehicle. Check for fluid leaks.

assembly. This component is typically not hydraulically activated; rather, the gearshift linkage moves the pawl into position to lock the output shaft of the transmission. Unless the customer's complaint indicates a problem with the parking mechanism, no test will detect a problem here.

Check the pawl assembly for excessive wear and other damage. Also, check to see how firmly the pawl is in place when the gear selector is shifted into the park mode. If the pawl can be moved out easily, it should be repaired or replaced.

Basic Diagnostics

Automatic transmission problems are commonly caused by poor engine performance, problems in the hydraulic system, abuse resulting in overheating, mechanical malfunctions, electronic failures, and/or improper adjustments.

Engine performance can affect torque converter clutch operation. If the engine is running too poorly to maintain a constant speed, the converter clutch will engage and disengage at higher speeds. The customer complaint may be that the vehicle vibrates.

If the vehicle has an engine performance problem, the cause should be found and corrected before any conclusions on the transmission are made. A quick way to identify if the engine is causing shifting problems is to connect a vacuum gauge to the engine and take a reading while the engine is running. The gauge should be connected to intake manifold vacuum. A normal vacuum gauge reading is steady at about 17 in. Hg (431.8 mm Hg). The rougher the engine runs, the more the gauge readings will fluctuate.

Visual Inspection

Diagnosis of transmission problems should continue with conducting a thorough visual inspection, checking the various linkage adjustments, retrieving all DTCs, and checking basic engine operation. Also, check the voltage of the battery as improper voltage can affect the performance of the transmission.

Fluid Leaks

Check all drivetrain parts for looseness and leaks. If the transmission fluid was low or there was no fluid, raise the vehicle and carefully inspect the transmission for signs of leakage. Leaks are often caused by defective gaskets or seals. Common sources of leaks are the oil pan seal, rear cover and final drive

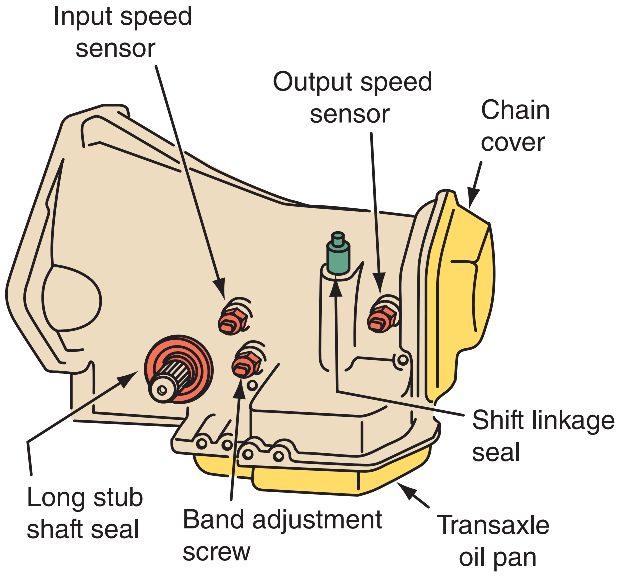

FIGURE 43–8 Possible sources of fluid leaks on this transaxle.

cover (on transaxles), extension housing, speedometer gear assembly, and electrical switches mounted into the housing **(Figure 43–8)**. The housing may have a porosity problem, allowing fluid to seep through the metal. Case porosity may be repaired with an epoxy sealer.

Oil Pan A common source of fluid leakage is between the oil pan and the transmission housing. If fluid is present around the rim of the pan, retorquing the pan bolts may correct the problem. If it does not correct the problem, the pan must be removed and a new gasket installed. Make sure the sealing surface of the pan is flat and capable of providing a seal before reinstalling it.

Torque Converter Torque converter problems can be caused by a leaking converter **(Figure 43–9)**. This type of problem may be the cause of customer complaints of slippage and a lack of power. To check the converter for leaks, remove the converter access cover and examine the area around the torque converter shell. An engine oil leak may be falsely diagnosed as a converter leak. The color of engine oil is different from that of transmission fluid and may help identify the true source of the leak. However, if the oil or fluid has absorbed much dirt, both will look the same. An engine leak typically leaves an oil film on the front of the converter shell, whereas a converter leak will cause the entire shell to be wet. If the transmission's oil pump seal is leaking, only the back side of the shell will be wet. If the converter is leaking or damaged, it should be replaced.

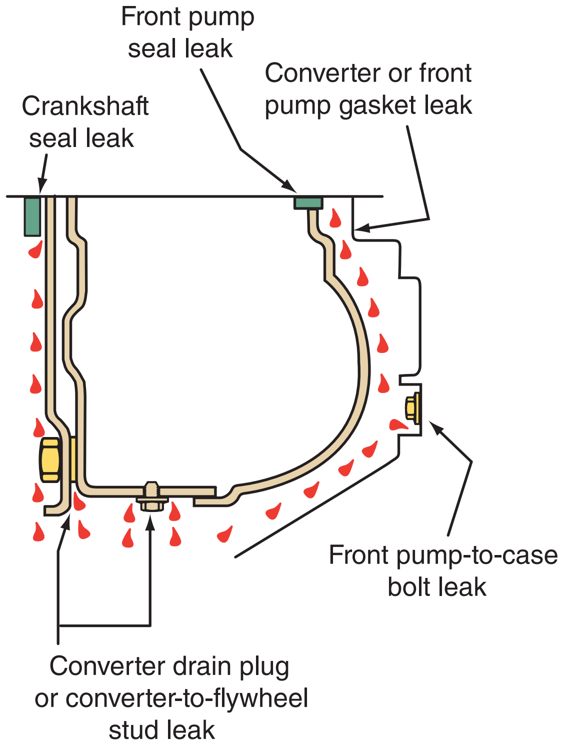

FIGURE 43–9 By determining the direction of fluid travel, the cause of a fluid leak around the torque converter can be identified.

Inspect the converter shell for swelling and signs of bluing. Both indicate that the converter has been too hot. Restrictions in the transmission cooler circuit and malfunctioning pressure valves can lead to an overheated converter.

Extension Housing An oil leak stemming from the mating surfaces of the extension housing and the transmission case may be caused by loose bolts. To correct this problem, tighten the bolts to the specified torque. Also, check for signs of leakage at the rear of the extension housing. Fluid leaks from the seal of the extension housing can be corrected with the transmission in the car. Often, the cause for the leakage is a worn extension housing bushing, which supports the sliding yoke of the drive shaft. When the drive shaft is installed, the clearance between the sliding yoke and the bushing should be minimal. If the clearance is satisfactory, a new oil seal will correct the leak. If the clearance is excessive, the repair requires that a new seal and a new bushing be installed.

Speed Sensor The vehicle's speedometer can be purely electronic, which requires no mechanical hookup to the transmission, or it can be driven, via a cable, off the output shaft. If the transmission is

equipped with a VSS, the bore and sensor can be a source of leaks. The sensor is retained in the bore with a retaining nut or bolt. An oil leak at the speedometer cable or VSS can be corrected by replacing the O-ring seal. Always lubricate the O-ring and sensor prior to installation.

Electrical Connections

Check all electrical connections to the transmission. Faulty connectors or wires can cause harsh or delayed and missed shifts. On transaxles, the connectors can normally be inspected through the engine compartment, whereas they can only be seen from under the vehicle on longitudinally mounted transmissions. To check the connectors, release the locking tabs and disconnect them, one at a time, from the transmission. Carefully examine them for signs of corrosion, distortion, moisture, and transmission fluid **(Figure 43–10)**. Carefully check the weather seals on all connectors. A connector or wiring harness may deteriorate if ATF reaches it. Also, check the connector at the transmission. Using a small mirror and flashlight may help you get a good look at the inside of the connectors. Inspect the entire transmission wiring harness for tears and other damage. Road debris can damage the wiring and connectors mounted underneath the vehicle.

Because the operation of the engine and transmission are integrated through the control computer, a faulty engine sensor or connector may affect the operation of the engine and the transmission. The various sensors and their locations can be identified by referring to the appropriate service information.

FIGURE 43–10 Carefully disconnect all connectors and inspect them.

The engine control sensors that are the most likely to cause shifting problems are the TP, MAP, and VSS.

Checking Transmission and Transaxle Mounts

The engine and transmission mounts on FWD cars are important to the operation of the transaxle. Any engine movement may change the effective length of the shift and throttle cables or wiring harnesses and therefore may affect the engagement of the gears. Delayed or missed shifts may result from linkage changes as the engine pivots on its mounts.

Visually inspect the mounts for looseness and cracks. With a pry bar, pull up and push down on the transaxle case while watching the mount **(Figure 43–11)**. If there is movement between the metal plate and its attaching point on the frame, tighten the attaching bolts.

Then, from the driver's seat, apply the foot brake, set the parking brake, and start the engine. Put the transmission into a forward gear and gradually increase the engine speed to about 1,500 to 2,000 rpm. Watch the torque reaction of the engine on its mounts. Repeat the check in reverse. If the engine's reaction to the torque appears to be excessive, broken or worn drivetrain mounts may be the cause.

If it is necessary to replace the transaxle mount, make sure you follow the manufacturer's recommendations for maintaining the alignment of the driveline. Failure to do so may result in poor gear shifting, vibrations, and/or broken cables. Some manufacturers recommend that a holding fixture or special bolt be used to keep the unit in its proper location.

FIGURE 43–11 All transmission and engine mounts should be carefully checked for cracks and damage.

Transmission Cooler and Line Inspection

Transmission coolers are a possible source of fluid leaks. The efficiency of the coolers is also critical to the operation and longevity of the transmission. Follow these steps when inspecting the transmission cooler and associated lines and fittings:

1. Check the engine's cooling system. The transmission cooler cannot be efficient if the engine's cooling system is defective. Repair all engine cooling system problems before continuing to check the transmission cooler.
2. Inspect the fluid lines and fittings between the cooler and transmission. Check these for looseness, damage, signs of leakage, and wear. Replace any damaged lines and fittings.
3. Inspect the engine's coolant for traces of transmission fluid. If ATF is present in the coolant, the transmission cooler leaks.
4. Check the transmission's fluid for signs of engine coolant. Water or coolant will cause the fluid to appear milky with a pink tint. This milky appearance is also an indication that the transmission cooler leaks and is allowing engine coolant to enter into the transmission fluid.

The cooler can be checked for leaks by disconnecting and plugging the transmission to cooler lines at the radiator. Then remove the radiator cap to relieve any pressure in the system. Tightly plug one of the ATF line fittings at the radiator. Using the shop air supply with a pressure regulator, apply 50 to 70 psi (3.52 to 4.92 kg/cm^2) of air pressure into the cooler at the other cooler line fitting **(Figure 43–12)**. Look into the radiator. If bubbles are observed, the cooler leaks.

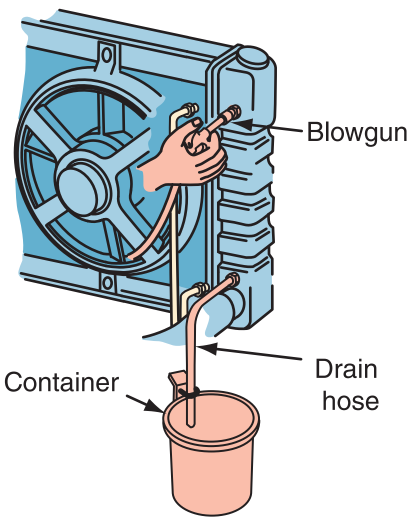

FIGURE 43–12 Shop air can be used to check a transmission for leaks and restrictions.

Road Testing the Vehicle

Critical to proper diagnosis of an automatic transmission is a road test. If the vehicle has an EAT, connect a scan tool with recording capabilities, if possible, before taking the drive. Also, find the appropriate chart that shows the activity of the various solenoids for the transmission **(Figure 43–13)**. Knowing their activity will help you determine if one or more of them are causing a shifting problem.

All transmission concerns should be verified attempting to duplicate the customer's concern. Knowing the exact conditions that cause the symptom will allow you to accurately diagnose the cause. Diagnosis becomes easy if you think about what is happening in the transmission when the problem occurs. If there is a shifting problem, think about the parts that are being engaged and disengaged.

Also, before beginning your road test, find and duplicate, from service information, the chart that shows the band and clutch application for different gear selector positions. Using these charts will greatly simplify your diagnosis of automatic transmission problems. It is also wise to have a notebook or piece of paper to jot down notes about the operation of the transmission.

Begin the road test with a drive at normal speeds to warm the engine and transmission. If a problem appears only when starting and/or when the engine and transmission are cold, record this symptom on the chart or in your notebook.

During the road test, the transmission should be operated in all possible modes and its operation noted. Check for proper gear engagement as the selector lever is moved to each gear position, including park. There should be no hesitation or roughness as the gears are engaging. Check for proper operation in all forward ranges, especially the upshifts and converter clutch engagement during light throttle operation. These shifts should be smooth and positive and occur at the correct speeds. These same shifts should feel firmer under medium to heavy throttle pressures. Transmissions equipped with a torque converter clutch should be brought to the specified apply speed and their engagement noted. Again, record the operation of the transmission in these different modes in your notebook or on the diagnostic chart. Also, the various computer inputs should be monitored and the readings recorded.

Force the transmission to kick down and pay attention to the quality of this shift. Manual downshifts should also be made at a variety of speeds.

The reaction of the transmission should be noted, as should all abnormal noises, and the gears and speeds at which they occur.

After the road test, check the transmission for signs of leakage. Any new leaks and their probable cause should be noted. Then compare your written notes from the road test to the information given in the service information to identify the cause of the malfunction. This information usually has a diagnostic chart to aid you in this process.

Diagnosis of Noise and Vibration Problems

Many noise and vibration problems that appear to be transmission related may be caused by problems in the engine, drive shaft, U-joints or CV joints, wheel bearings, wheel/tire imbalance, or other conditions. Problems in those areas can lead customers and, unfortunately, some technicians, to mistakenly

suspect that the problems are caused by the transmission or torque converter. The entire driveline should be checked before assuming that the noise is transmission related.

Common transmission noise and vibrations, and their typical cause, are shown in **(Figure 43–14)**. As can be seen, they can be caused by faulty bearings, damaged gears, worn or damaged clutches and bands, or a bad oil pump as well as contaminated fluid or improper fluid levels.

Most vibration problems are caused by an unbalanced torque converter assembly, a loosely mounted torque converter, a loose or cracked flexplate, torque converter, or a faulty output shaft. The key to determining the cause of the vibration is to pay particular attention to the vibration in relationship to engine and vehicle speed. If the vibration changes with a change in engine speed, the cause of the problem is probably the torque converter. If the vibration changes with vehicle speed, the cause is probably the output shaft or the driveline connected to it. The latter can be a bad extension housing bushing or universal joint, which could become worse at higher speeds.

To determine if the problem is caused by the transmission or the driveline, put the transmission in gear and apply the foot brakes. If the noise is no longer evident, the problem can be in the driveline or the output of the transmission. If the noise is still present, the problem must be in the transmission or torque converter.

Some lab scopes have the ability to measure vibrations, analyze the data, and plot the vibration characteristics on the scope. This ability can be very

Engine speed sensitive whine	Torque converter is faulty Faulty pump
Popping noise	Pump cavitation—bubbles in the ATF Damaged fluid filter or filter seal
Buzz or high-frequency rattle whine or growl	Cooling system problem Stretched drive chain Broken teeth on drive and/or driven sprockets Nicked or scored drive and/or driven sprocket bearing surfaces Pitted or damaged bearing surfaces
Final drive hum	Worn final drive gear assembly Worn or pitted differential gears Damaged or worn differential gear thrust washers

FIGURE 43–14 A basic symptom-based diagnostic chart.

useful when trying to isolate the cause of a driveline vibration.

Noise problems are also best diagnosed by paying a great deal of attention to the speed and the conditions at which the noise occurs. If the noise is engine speed related and is present in all gears, including park and neutral, the oil pump is the most probable source because it rotates whenever the engine is running. However, if the noise is engine speed related and is present in all gears except park and neutral, the most probable sources of the noise are those parts that rotate in all gears, such as the drive chain, the input shaft, and the torque converter.

Noises that only occur when a particular gear is operating must be related to those parts responsible for providing that gear, such as a brake or clutch. Often the exact cause of noise and vibration problems can only be identified through a careful inspection of a disassembled transmission.

Checking the Torque Converter

Many transmission problems are related to the operation of the torque converter. Normally, torque converter problems will cause abnormal noises, poor acceleration in all gears, normal acceleration but poor high-speed performance, or transmission overheating.

If the vehicle lacks power during acceleration, it has a restricted exhaust or the torque converter's one-way stator clutch is slipping. To determine which of these problems is causing the power loss, test for a restricted exhaust first. Other possible causes of this problem include a restricted air or fuel filter and a defective fuel pump.

If there is no evidence of a restricted exhaust, it can be assumed that the torque converter's stator clutch is slipping and not allowing any torque multiplication to take place in the converter. To correct this problem, the torque converter should be replaced.

If the engine's speed flares up during acceleration in drive and does not have normal acceleration, the clutches or bands in the transmission are slipping. This symptom is similar to the slipping of a clutch in a manual transmission. Often this problem is mistakenly blamed on the torque converter.

Complaints of thumping or grinding noises are often thought to be caused by the torque converter (T/C), when they are actually caused by bad thrust washers or damaged gears and bearings in the transmission. Nontransmission problems, such as bad CV joints and wheel bearings, also cause these noises.

A faulty engine damper can feel like a bad T/C, allowing vibrations that seem to be related to the torque converter. These vibrations can be caused by an out of balance torque converter. If the T/C is not properly balanced, the vibration will increase at higher speeds and while the transmission is in gear.

Checking the TCC

During the road test, check to see if the TCC engages and disengages. Engagement should be smooth and free of abnormal vibrations and noise. If the clutch prematurely engages or is not being applied by full pressure, a shudder or vibration results from the rapid grabbing and slipping of the clutch. If the shudder is only noticeable during clutch engagement, the problem is typically the converter. When the shudder is evident after the engagement of the clutch; the engine, transmission, or another component of the driveline may be the cause.

A shudder when the TCC is being engaged or disengaged can be caused by an out-of-round torque converter or contaminated clutch frictional material. An out-of-round converter prevents full clutch engagement.

If the clutch does not engage, check the TCC solenoid circuit for power and excessive voltage drops. The solenoids should drop very close to source voltage. If the solenoid is electrically sound, suspect clutch material, dirt, or other material plugging the solenoid valve passages. If blockage is found, attempt to flush the valve with clean ATF. If the solenoid has a filter assembly **(Figure 43–15)**,

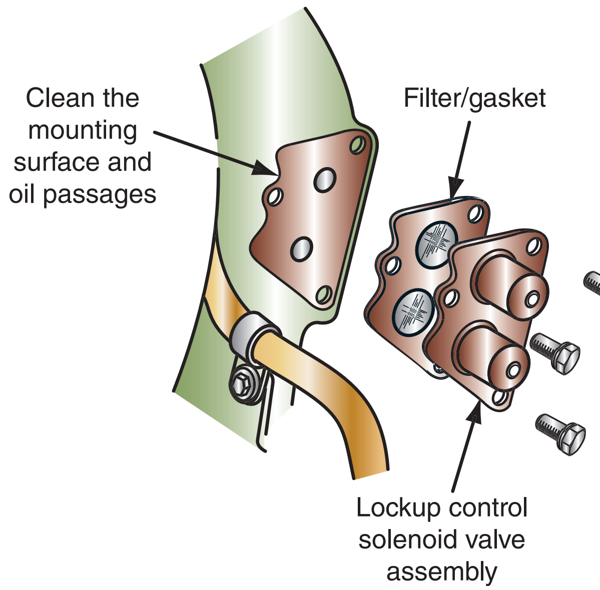

FIGURE 43–15 Some torque converter clutches have a replaceable filter.

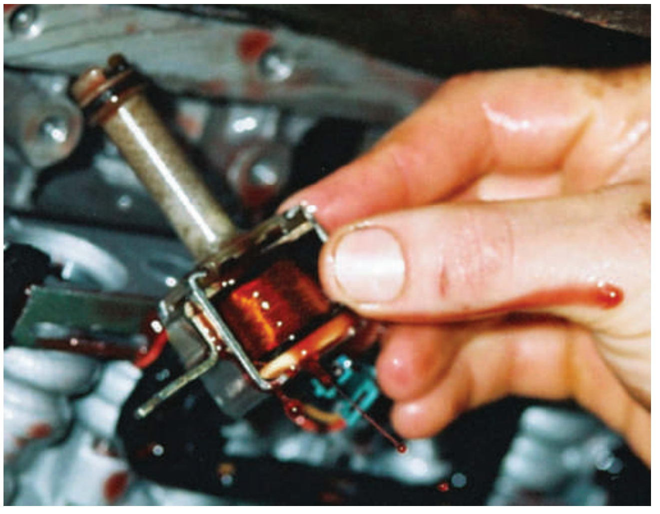

FIGURE 43-16 A TCC solenoid.

replace the filter after cleaning the fluid passages. If the blockage cannot be removed, replace the solenoid **(Figure 43–16)**.

The TCC also may not apply because of fluid leaking from the converter or past its seals, or a severely worn TCC disc or friction material has fallen off the clutch disc.

If the TCC stays applied and tends to stall the engine at a stop, the problem may be a damaged piston plate or the plate is stuck to the T/C cover. These problems can be caused by overheating the converter. Look at the converter for signs of heat to verify this problem. This problem can also be caused by the lack of end clearance inside the converter. In either case, the T/C should be replaced.

If the concern with the TCC is electrical, all related inputs and outputs should be tested with the appropriate meter. A scan tool should be used to retrieve all DTCs **(Figure 43–17)**. The scan tool should also be used to monitor the serial data while the vehicle is taken on a road test.

Most systems have the provision for operating outputs from the scan tool. This feature allows you to engage and disengage the TCC so its action can be felt and heard.

Stall Test

To test the torque converter, many technicians perform a stall test. The stall test checks the holding capacity of the converter's stator overrunning clutch assembly as well as the clutches and bands in the transmission. Some manufacturers do not

FIGURE 43-17 A sample of some TCC-related DTCs.

Caution! If a stall test is not correctly conducted, the converter and/or transmission can be damaged.

recommend the stall test. Rather, diagnosis should be based on the symptoms of the problem.

To conduct a stall test, connect a tachometer to the engine and position it so that it can be easily read from the driver's seat. Set the parking brake, raise the hood, and place blocks in front of the vehicle's non-driving tires. Conduct the test outdoors, if possible, especially if it is a cold day. If the test is conducted indoors, place a large fan in front of the vehicle to keep the engine cool. With the engine running, press and hold the brake pedal. Then move the gear selector to the drive position and press the throttle pedal to the floor. Hold the throttle down for 2 seconds then note the tachometer reading and immediately let off the throttle pedal and allow the engine to idle. Compare the measured stall speed to specifications.

Warning! Make sure no one is around the engine or the front of the vehicle while a stall test is being conducted. A lot of stress is put on the engine, transmission, and brakes during the test. If something lets go, somebody can get seriously hurt.

Caution! To prevent serious damage to the transmission, follow these guidelines while conducting a stall test:

1. Never conduct a stall test if there is an engine problem.
2. Check the fluid levels in the engine and transmission before conducting the test.
3. Ensure that the engine is at normal operating temperature during the test.
4. Never hold the throttle wide open for more than 5 seconds during the test.
5. Do not perform the test in more than two gear ranges without driving the vehicle a few miles to allow the engine and transmission to cool down.
6. After the test, allow the engine to idle for a few minutes to cool the transmission fluid before shutting off the ignition.

The engine will reach a specific speed if the torque converter and transmission are functioning properly. If the tachometer indicates a speed above or below specifications, a possible problem exists in the transmission or torque converter. If a torque converter is suspected as being faulty, it should be removed and the one-way clutch checked on the bench.

A restricted exhaust or slipping stator clutch is indicated if the stall speed is below the specifications. If the stator's one-way clutch is not holding, ATF leaving the turbine of the converter works against the rotation of the impeller and slows down the engine. Both of these problems cause poor acceleration. If the stall speed is only slightly below normal, the engine is probably not producing enough power and should be diagnosed and repaired.

If the vehicle has poor acceleration but had good results from the stall test, suspect a seized one-way clutch. Excessively hot ATF in the transmission is a good indication that the clutch is seized. However, other problems can cause these same symptoms; therefore, be careful during your diagnosis.

If the stall speed is above specifications, the bands or clutches in the transmission may be slipping and not holding properly.

A stall test will generate a lot of noise, most of which is normal. If you hear any metallic noises during the test, however, diagnose the source of these noises. Operate the vehicle at low speeds on a hoist with the drive wheels free to rotate. If the noises are still present, the source of the noises is probably the torque converter.

TC-Related Cooler Problems

Vehicles equipped with a TCC may stall when the transmission is shifted into reverse gear. The cause of this problem may be plugged transmission cooler lines, or the cooler itself. Fluid normally flows from the torque converter through the transmission cooler. If the cooler passages are blocked, fluid is unable to exhaust from the torque converter and the TCC's piston remains engaged. When the clutch is engaged, there is no vortex flow in the converter and therefore little torque multiplication takes place in the converter.

To verify that the transmission cooler is plugged, disconnect the cooler return line from the radiator or cooler. Connect a short piece of hose to the outlet of the cooler and allow the other end of the hose to rest inside an empty container. Start the engine and measure the amount of fluid that flows into the container after twenty seconds. Normally, 1 quart of

fluid should flow into the container. If less than that filled the container, a plugged cooler is indicated.

If the cooler is plugged, disconnect the cooler lines at the transmission and the radiator. Blow air through the cooler, one end at a time, then through the cooler lines. The air will clear large pieces of debris from the cooler. Always use low air pressure, no more than 50 psi (3.5 kg/cm^2). Higher pressures may damage the cooler. If there is little airflow through the cooler, the radiator or external cooler must be removed and flushed or replaced.

Diagnosing Hydraulic and Vacuum Control Systems

The best way to identify the exact cause of the problem is to use the results of the road test, logic, and the oil circuit charts for the transmission being worked on. Before doing this, however, always check all sources for information about the symptom first. Also, make sure to check the basics: trouble codes in the computer, fluid level and condition, leaks, and mechanical and electrical connections.

Using the oil circuits available in the service information, you can identify which valves and apply devices should be operating in each particular gear selector position. Through a process of elimination, you can identify the most probable cause of the problem.

In most cases, the transmission or transaxle is removed to repair or replace the items causing the problem. However, some transmissions allow for a limited amount of service to the apply devices and control valves.

Mechanical and/or vacuum controls can also contribute to shifting problems. The condition and adjustment of the various linkages and cables should be checked whenever there is a shifting problem. If all checks indicate that the problem is either an apply device or in the valving, an air pressure test can help identify the exact problem. Air pressure tests are also performed during disassembly to locate leaking seals and during reassembly to check the operation of the clutches and servos.

Pressure Tests

If you cannot identify the cause of a transmission problem from your inspection or road test, a pressure test should be conducted. This test measures the fluid pressure of the different transmission circuits during the various operating gears and gear selector positions **(Figure 43–18)**. The number of hydraulic circuits that can be tested varies with the different makes and models of transmissions. However, most transmissions are equipped with pressure taps, which allow the pressure test equipment to be connected to the transmission's hydraulic circuits **(Figure 43–19).**

Before conducting a pressure test on an electronic automatic transmission, check and correct all trouble codes retrieved from the system. Also make sure the transmission fluid level and condition are okay and that the shift linkage is in good order and properly adjusted.

The test is best conducted with three pressure gauges, but two will work. Two of the gauges should read up to 400 psi (28 kg/cm^2) and the other to 100 psi (7 kg/cm^2). The two 400 psi (28 kg/cm^2) gauges are usually used to check mainline and an individual circuit, such as mainline and direct or forward circuits. If a circuit is 15 psi (1 kg/cm^2) lower than mainline pressure when they are both tested at exactly the same time, a leak is indicated. A 100 psi (7 kg/cm^2) gauge may be used be used on TV and governor circuits.

The pressure gauges are connected to the pressure taps in the transmission housing and routed so that the gauges can be seen by the driver. The vehicle is then road tested and the gauge readings observed during the following operational modes: slow idle, fast idle, and WOT. Depending on the vehicle, pressure tests may be able to be performed through the scan tool **(Figure 43–20)**. With pressure gauges connected, use the scan tool to increase and decrease line pressure and compare to specifications. Perform the test several times to be sure to achieve accurate readings.

During the road test, observe the starting pressures and the steadiness of the increases that occur with slight increases in load. The pressure drops as the transmission shifts from one gear to another also should be noted. The pressure should not drop more than 15 psi (1 kg/cm^2) between shifts.

Any pressure reading not within the specifications indicates a problem **(Figure 43–21)**. Typically, when the fluid pressures are low, there is an internal leak, clogged filter, low oil pump output, or faulty pressure regulator valve. If the pressure increased at the wrong time or the pressure was not high enough, sticking valves or leaking seals are indicated. If the pressure drop between shifts was greater than approximately 15 psi (1 kg/cm^2), an internal leak at a servo or clutch seal is indicated. Always check the manufacturer's specifications for maximum drop off.

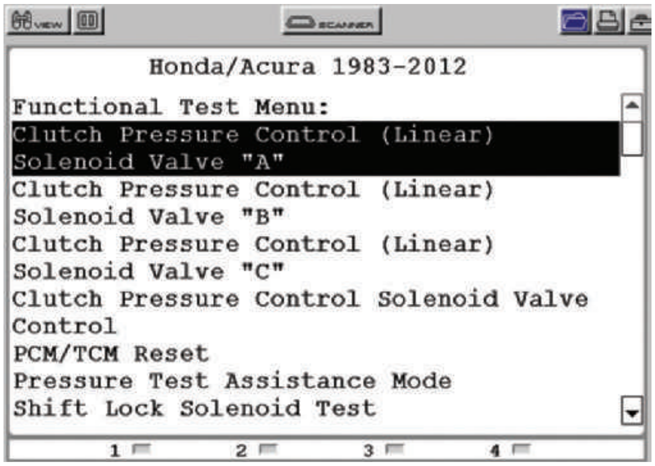

FIGURE 43-20 Solenoid testing with a scan tool.

On transmissions equipped with an electronic pressure control (EPC) solenoid, if the line pressure is not within specifications, the EPC pressure needs to be checked. To do this, connect the pressure gauge to the EPC tap. Start the engine and check EPC pressure, then compare it to specifications. If the pressure is not within specifications **(Figure 43–22)**, follow the procedures for testing the EPC. If the pressure is okay, there is a mainline pressure problem.

If the pressure tests suggest a governor or governor drive problem, it should be removed, disassembled, cleaned, and inspected. However, electronically controlled transmissions do not rely on the hydraulic signals from a governor; rather, they rely on the electrical signals from speed and load sensors. These send a signal to the TCM when gears should be shifted.

Some transmissions require that the transmission be removed to service the governor. In other transmissions, it can be serviced by removing the extension housing or oil pan, or by detaching an external retaining clamp and then removing the unit.

Common Problems

The following problems and their causes are given as examples. The actual causes of these types of problems vary with the different models of transmissions. Refer to the appropriate Band and Clutch Application Chart while diagnosing shifting problems. Doing so allows you to identify the cause of the shifting problems through the process of elimination.

Normally, if the shift for all forward gears is delayed, the clutch that is applied in all forward gears may be slipping. Likewise, if the slipping occurs in one or more gears but not all, suspect the clutch that is applied only during those gear ranges.

It is important to remember that delayed shifts or slippage may also be caused by leaking hydraulic circuits or sticking spool valves in the valve body. Since the application of bands and clutches is controlled by the hydraulic system, improper pressures will cause shifting problems. Other components of the transmission can also contribute to shifting problems. For example, on transmissions equipped with a vacuum modulator, if upshifts do not occur at the specified speeds or do not occur at all, the modulator may be faulty or the vacuum supply line may be leaking.

Valve Body

If the pressure problem was associated with the valve body, a thorough disassembly, cleaning in fresh solvent, careful inspection, and the freeing and polishing of the valves may correct the problem. Disconnect the lever and detent assemblies attached to the valve body, and then remove the valve body screws. Before lowering the valve body and separating the assembly, hold the assembly with the valve body on the bottom and the transfer and separator plates on top. Holding the assembly in this way reduces the chances of dropping the steel balls located in the valve body. Lower the valve body and note where these steel balls are located in the valve body **(Figure 43–23)**, then remove them and set them aside along with the various screws.

After all of the valves and springs **(Figure 43–24)** have been removed from the valve body, soak the

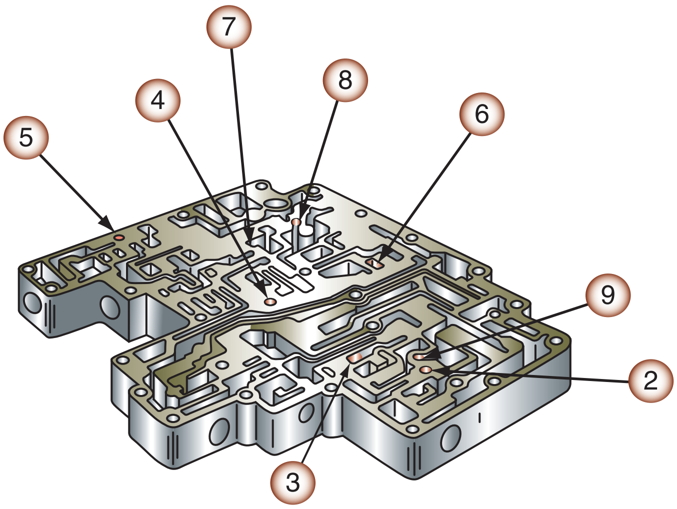

FIGURE 43–23 Location of the check balls in a typical valve body.

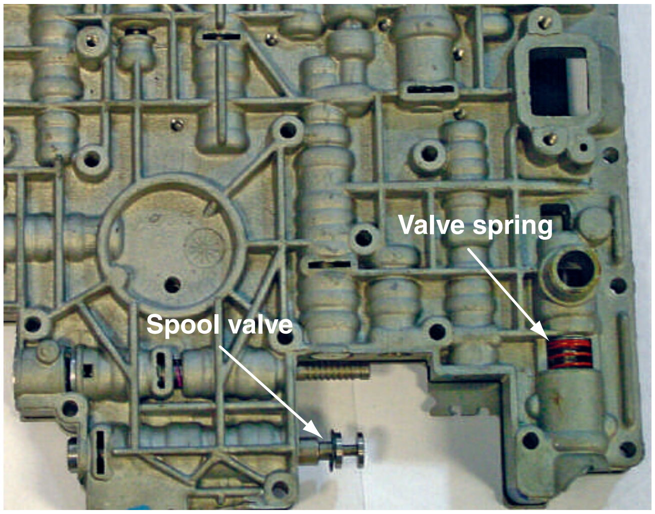

FIGURE 43–24 Examples of a spool valve and return spring in a valve body.

FIGURE 43–25 To remove the servo in some transmissions, the retaining snapring must be removed.

valve body, separator, and transfer plates in mineral spirits for a few minutes. Thoroughly clean all parts and make sure all passages within the valve body are clear and free of debris. Carefully blow-dry each part individually with dry compressed air. Never wipe the parts of a valve body with a wiping rag or paper towel. Lint from either will collect in the valve body passages and cause shifting problems. As the parts of the valve body are dried, place them in a clean container.

Examine each valve for nicks, burrs, and scratches. Check that each valve properly fits into its respective bore. If a valve cannot be cleaned enough to move freely in its bore, the valve body is normally replaced. Individual valve body parts are available, as well as bore reamers. Care must be taken when rebuilding valve bodies.

During reassembly of the valve body, lube the valves with fresh ATF. Check the valve body gasket (if used) to make sure it is the correct one by laying it over the separator plate and holding it up to the light. No oil holes should be blocked. Then install the bolts to hold valve body sections together and the valve body to the case. Tighten the bolts to the torque specifications to prevent valve body warpage and possible leakover.

Servo Assemblies

On some transmissions, the servo assemblies are serviceable with the transmission in the vehicle **(Figure 43–25)**. Others require the complete disassembly of the transmission. Internal leaks at the servo or clutch seal will cause excessive pressure drops during gear changes.

When removing the servo, check both the inner and outer parts of the seal for wet oil that means leakage. When removing the seal, inspect the sealing surface, or lips, before washing **(Figure 43–26)**. Look for unusual wear, warping, cuts and gouges, or particles embedded in the seal.

The servo piston, spring, piston rod, and guide should be cleaned and dried. Then check the sealing rings to make sure they are able to turn freely in the groove of the piston ring. These seal rings are not typically replaced unless they are damaged, so carefully inspect them. Check the servo piston for cracks, burrs, scores, and wear. Inspect the servo cylinder for scores or other damage. Move the piston rod through the piston rod guide and check for freedom of movement. If all of the parts are in good condition, the servo assembly can be reassembled.

FIGURE 43–26 When removing the servo assembly, carefully inspect all parts.

Lubricate the sealing ring with ATF and carefully install it on the piston rod. Lubricate and install the piston rod guide with its snapring into the servo piston. Then, install the servo piston assembly, return spring, and piston guide into the servo cylinder. Some servos are fitted with rubber lip seals that should be replaced. Lubricate and install the new lip seal. On lip seals, make sure the spring is seated around the lip and that the lip is not damaged.

Band Adjustment

On some transmissions, slippage during shifting can be corrected by adjusting the holding bands. To help identify if a band adjustment will correct the problem, refer to the written results of your road test. Compare your results with the Clutch and Band Application Chart in the service information. If slippage occurs when there is a gear change that requires the holding by a band, the problem may be corrected by tightening the band.

On some vehicles, the bands can be adjusted externally with a torque wrench. On others, the transmission fluid must be drained and the oil pan removed. Locate the band-adjusting nut **(Figure 43–27)**, then clean off all dirt on and around the nut. Now, loosen the band-adjusting bolt locknut and back it off approximately five turns. Use a calibrated pound-inch torque wrench to tighten the adjusting bolt to the specified torque. Then back off the adjusting screw the specified number of turns and tighten the adjusting bolt locknut while holding the adjusting stem stationary. Reinstall the oil pan with a new gasket and refill the transmission with fluid. If the transmission problem still exists, an oil pressure test or transmission teardown must be done.

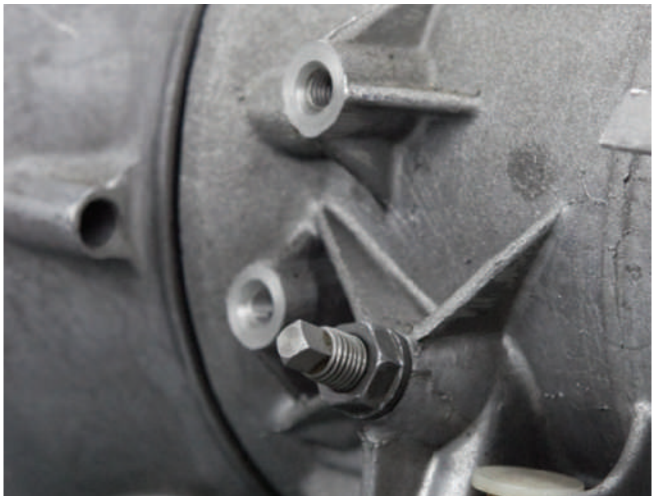

FIGURE 43–27 An example of the location of an external band adjusting screw.

Warning! Do not excessively back off the adjusting stem as the anchor block may fall out of place. It will then be necessary to remove and disassemble the transmission to fit it back in place.

Linkages

Many transmission problems are caused by improper adjustment of the linkages. Older transmissions have either a cable or a rod-type gear selector linkage and also have throttle valve linkage or an electric switch connected to the throttle to control forced downshifts.

Transmission Range Switch

The transmission range (TR) switch or sensor sends gear shifter location to the TCM and PCM. A faulty switch can cause the transmission to not upshift, not stay in gear, delay gear engagement, and allow the engine to start in positions other than park and neutral.

To check the TR sensor, connect a scan tool and prepare it to read the transmission data. Move the gear selector through its various positions and see if the scan tool is displaying the selected location. Depending on the type of sensor, you may need a digital multimeter (DMM) to check the resistance through each position of the switch. Always refer to the manufacturer's service procedures for proper testing information.

The TR sensor will not work properly if the gear shift linkage is damaged or out of adjustment.

Gear Selector Linkage

Many transmissions have a shift cable. The cable connects the gear shifter to the transmission's shift lever. The shift lever is connected to the manual shift valve. This valve directs fluid through the valve body according to the position of the shift lever.

Some automatic transmissions have no linkage, rather the gear shift works as an input device for the TCM or PCM.

A worn or misadjusted gear selection linkage will affect transmission operation. The transmission's manual shift valve must completely engage the selected gear **(Figure 43–28)**. Partial manual shift valve engagement will not allow the proper amount of fluid pressure to reach the rest of the valve body. If the linkage is misadjusted, poor gear engagement,

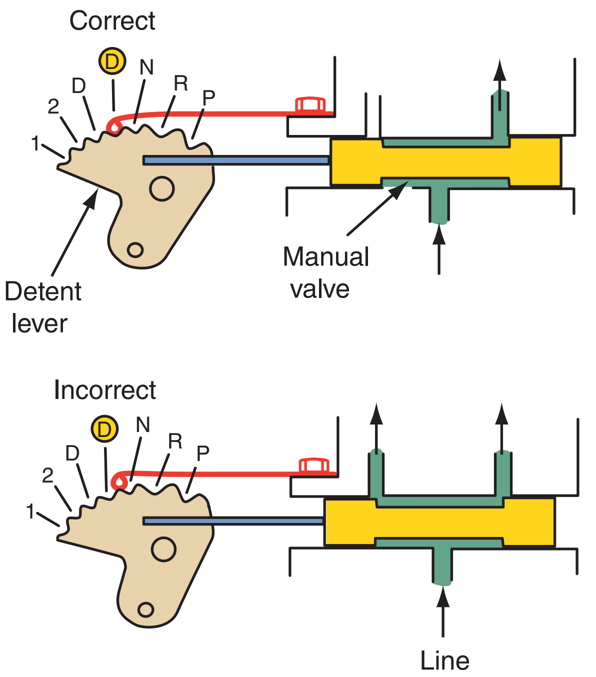

FIGURE 43-28 Incorrect linkage adjustments may cause the manual shift valve to be positioned improperly in its bore and cause slipping during gear changes.

slipping, and excessive wear can result. The gear selector linkage should be adjusted so the manual shift valve detent position in the transmission matches the selector level detent and position indicator.

To check the adjustment of the linkage, move the shift lever from park to the lowest drive gear. Detents should be felt at each of these positions. If the detent cannot be felt, the linkage needs to be adjusted. While moving the shift lever, pay attention to the gear position indicator. Although the indicator will move with an adjustment of the linkage, the pointer may need to be adjusted so that it shows the exact gear after the linkage has been adjusted.

Replacing, Rebuilding, and Installing a Transmission

Obviously, in order to rebuild or service a transmission, it must be removed. The procedure for this is very similar to removing a manual transmission or transaxle. The exact procedure for removing a transmission will vary with each year, make, and model of vehicle. Always refer to the service information for the correct procedure.

GO TO Chapter 39 for details on removing and installing a transmission.

Before removing the transmission, remove the torque converter access cover. Check for loose torque converter bolts. Then rotate the engine and watch the movement of the T/C. If it wobbles, this may be caused by a damaged flexplate or converter.

Place an index mark on the converter and the flexplate to ensure the two will be properly mated during installation. Using a flywheel turning tool, rotate the flywheel until some of the converter-to-flexplate bolts are exposed. Loosen and remove the bolts. Once the bolts are removed, slide the converter back into the transmission.

Once the vehicle is in position, disconnect all transmission linkages connected to the engine. Also remove the ATF dipstick. Plug the cooler line fittings on the housing and the lines. Then proceed to remove the transmission.

Inspecting the Torque Converter

After the transmission has been removed:

- Inspect the flexplate for evidence of cracking or other damage.
- Check the condition of the starter ring gear teeth and make sure the gear is firmly attached to the flexplate.
- Inspect the drive studs or lugs used to attach the converter to the flexplate.
- Check the shoulder area around the lugs and studs for cracked welds or other damage.
- Inspect the converter attaching bolts or nuts and replace them if they are damaged.
- Check the T/C for ballooning; this is caused by excessive pressure. If the converter is ballooned, it should be replaced and the cause of the high pressure corrected.
- Check the converter's balance weights to make sure they are still firmly attached to the unit.

Caution! Always begin by disconnecting the battery ground cable. This is a safety-related precaution to help avoid any electrical surprises when removing starters or wiring harnesses. It is also possible to send voltage spikes, which may kill the PCM if wiring is disconnected when the battery is still connected.

- Check the pilot of the converter for wear and other damage.
- Check the area around the pilot for cracks.
- Check the drive hub of the torque converter for wear and other damage **(Figure 43–29)**.
- Check for excessive runout of the flexplate and the converter's hub with a dial indicator.

In general, a torque converter should be replaced if there is fluid leakage from its seams or welds, loose drive studs, worn drive stud shoulders, stripped drive stud threads, heavily grooved hub, or excessive hub runout. The following additional tests of the T/C can be conducted to determine its condition:

- Stator one-way clutch check
- Internal interference check
- End play check
- Converter leakage tests

Summary of T/C Checks

These conditions suggest that the converter should be replaced:

- If there is a stator clutch failure.
- If there is internal interference.
- If the transmission's front pump is badly damaged.
- If the converter hub is severely damaged or scored.
- If there are signs of external fluid leaks.
- If the drive studs or lugs are damaged or loose.
- If there are signs of overheating.
- If heavy amounts of metal were found in the fluid.
- If any damage is evident that the converter is no longer balanced.

Although some specialty shops will rebuild a converter, nearly all technicians replace the converter when any of the above exists. This is especially true of converters with a clutch. Rebuilding a converter is not a normal task for an automobile technician. This procedure requires special equipment and knowledge, do not attempt to repair a faulty converter.

FIGURE 43–29 Check the oil pump and input shaft mating areas of the torque converter.

Transmission Overhaul

The exact procedure for overhauling a transmission depends solely on the specific transmission as well as the problems that the transmission may have. Always refer to the service information for the procedures for a specific transmission/ transaxle.

The following guidelines will help you service any transmission:

- After the unit has been removed from the vehicle, secure it in a suitable holding fixture.
- Remove the torque converter if it has not been already removed.
- Check and record the end play of the input shaft, before unbolting and removing the oil pan and gasket **(Figure 43–30)**.
- Remove the oil pan, oil filter, and all components readily accessible at this point.
- If the transaxle is fitted with a drive chain, inspect it for side play and stretch **(Figure 43–31)**.
- If the unit is a transaxle, remove the differential assembly.

GO TO Chapter 39 for information on checking and servicing final drive units in a transaxle.

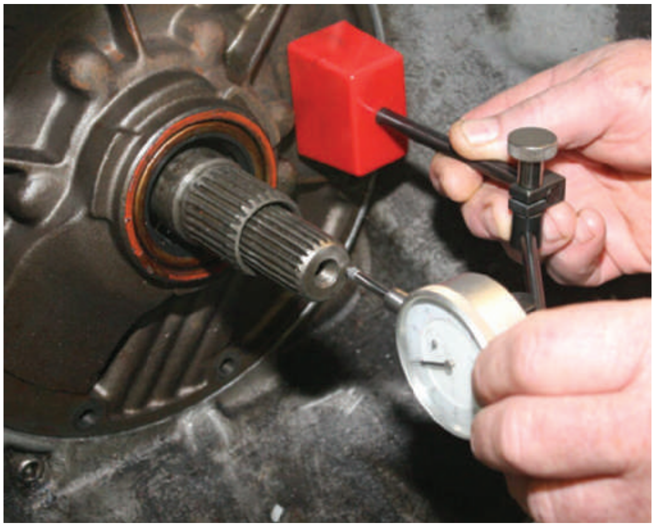

FIGURE 43–30 Before and after taking apart a transmission, check the end play of the input shaft.

FIGURE 43–31 While removing the drive chain from a transaxle, make sure you check it for damage and stretch.

- Before removing and disassembling the oil pump, mark the gears with machinist bluing ink or paint first. This ensures proper reassembly.
- Measure the clearances within the oil pump.
- Some oil pumps have a wear plate. The plate should be carefully inspected for damage and distortion. The plate should not be scored, nicked, or have grooves cut into it. The thickness of the plate at the wear area should be measured and compared to specifications.
- The bushing of the oil pump should be carefully checked and should be replaced if it is damaged or worn. The best way to determine if it is worn is to measure the inside diameter. If the measurement exceeds specifications, the bushing should be replaced.
- To replace the bushing, remove all gears from the pump's body. Support the body so both ends of the bushing's bore are away from the bench. Install the removal tool into the bore and press or drive the bushing out of the bore. Clean the bore and then press or drive the bushing into the bore.
- Check all pumps, valve bodies, and cases for warpage and ensure that they are flat filed to take off any high spots or burrs prior to reassembly.
- When removing the check balls and springs from the valve body, note their exact location and count them as they are removed.
- Check each spring for signs of distortion.
- Examine each valve for nicks, burrs, and scratches **(Figure 43–32)**.
- Check the oil passages in the upper and lower valve bodies for varnish deposits, scratches, or other damage that could restrict the movement of the valves. Make sure all fluid drain back openings are clear and have no varnish or dirt buildup.
- Band servos and accumulators are basically pistons with seals in a bore held in position by springs and retaining bolts or snaprings. Some pistons have cast iron seal rings that may not need replacement but rubber and elastomer seals should always be replaced.
- To disassemble an accumulator, depress the piston to remove the accumulator cover snapring. If the piston assembly is retained by a cover, unbolt the cover. Depending on the transmission, a special tool may be required to keep the spring compressed so the cover can be removed.
- Note the direction of the piston during the teardown, it is possible to install some pistons upside down. It is common for manufacturers to mate servo piston assemblies with accumulators. A servo is disassembled in a similar way as an accumulator. Some have two or more pistons and four or five fluid passages and fluid control orifices or check balls inside them. Make sure you do not mix the parts. Also note the exact location of the check balls.
- Inspect the outside area of the servo/accumulator seal. If it is wet, determine if the oil is leaking out or if it is merely a lubricating film of oil. Check both the inner and outer parts of the seal for wet oil which means leakage. When removing the seal, inspect the sealing surface or lips. Look for unusual wear, warping, cuts and gouges, or particles embedded in the seal.
- The accumulator or servo's piston, spring, piston rod, and guide should be cleaned and dried. Check the piston for cracks, burrs, scores, and

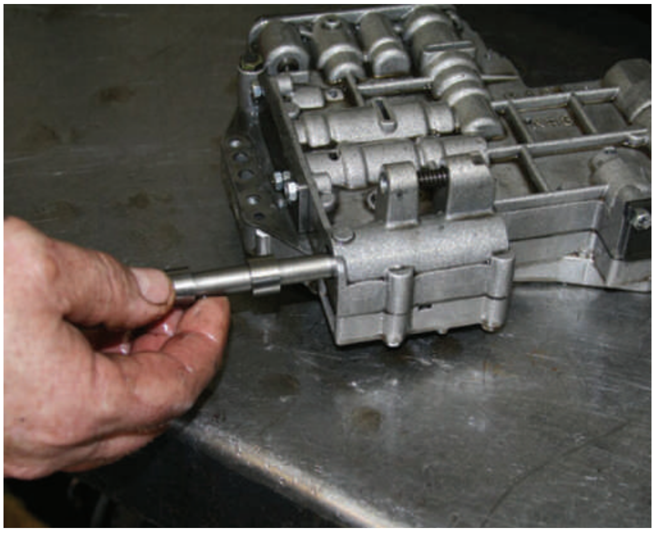

FIGURE 43–32 When removing vales from the valve body, check them for damage.

wear. The seal groove should be free of nicks or any imperfection that might pinch or bind the seal. Clean up any problems with a small file. The piston ring should rotate freely in its groove. If it does not, clean and inspect the grooves. Replace the piston ring during reassembly.

- Check the condition of the servo/accumulator pins. Look for signs of wear and damage. Also, check the fit of the pins and pistons in the case. The bores in the case should not allow the pins and pistons to wobble. If they do, they are worn or the bores in the case are worn.
- Inspect the servo or accumulator spring for cracks. Also, check the area where the spring rests against the case or piston. The spring may wear a groove; make sure the piston or case material has not worn too thin.
- Inspect the servo cylinder and other parts for wear, scores or other damage. Move the piston rod through the piston rod guide and check for freedom of movement. Replace all other components as necessary, and then reassemble the servo assembly.
- When removing and disassembling a multiple-disc assembly, use the correct puller and spring compressor. Measure the assembled clutch pack clearance. If the clearance is not correct, replace the pressure plate or snap ring that holds the pack in place to correct the clearance.
- Inspect the planetary gears for wear and signs of damage or discoloration. Make sure the planetary pinions spin freely but are not loose on the shaft. Measure planetary gear end play with feeler gauges and compare to specifications.
- Keep every part absolutely clean and air dry all parts. Only use lint-free rags to wipe parts off; lint can collect and damage the transmission.
- Check all of the threaded holes and related bolts and screws for damaged threads.
- Check the end play of each shaft as it is being assembled.
- Make sure that the correct size thrust washers are used throughout the transmission **(Figure 43–33)**.
- Soak all friction materials in clean ATF for at least 30 minutes prior to installing them.
- Coat the thrust washers, bearings, and bushings with transgel before putting them into position if specified by the service information.
- Typically to remove and install a one-way clutch, its retainer needs to be removed. Rotate the clutch clockwise until it lines up with the roller clutch cam ramps. Then remove the roller clutch from the inside of the roller clutch cam.

FIGURE 43–33 Make sure all thrust washers and bearings are the correct thickness before assembling the transmission.

- One-way clutches should be inspected for wear or damage, spline damage, surface finish damage, and damaged retainers and grooves. All smooth surfaces should be checked for any imperfections.
- All rollers and races that show any type of damage or surface irregularities should be replaced. Check the folded springs for cracks, broken ends, or flattening out. Replace all distorted or otherwise damaged springs.
- When reassembling a roller clutch, make sure the rollers and springs are facing the correct direction. If they are reversed the clutch will not lock in either direction.
- To reassemble the roller clutch assembly, press the clutch assembly onto the housing.
- Once the one-way clutches are ready for installation, verify that they overrun in the proper direction. Most one-way clutches have some marking that indicates which direction the clutch should be set. During installation, use a new retaining snapring.
- Solid sealing rings are commonly used in transmissions. These rings are made of a Teflon-based material and are never reused. To remove them, pry them out of their groove and carefully cut through the seal. Installing a new seal requires two tools: an installation tool and a resizing tool. To install a Teflon seal, warm the new seal in hot water to soften the material; this will make installation easier. Lubricate the new seal and tool. Slide the seal over the tool and seat it into its groove on

the hub or shaft. Inspect all bushings that may be inserted into the planetary gearsets. These are commonly found in sun gears. Measure the inside diameter and compare that dimension to specifications. If the diameter exceeds those specifications, replace the gear assembly.

- When tightening any fastener that directly or indirectly involves a rotating shaft, rotate the shaft during and after tightening to ensure that the part does not bind.
- Always use new gaskets and seals throughout the transmission.
- Make sure the differential and final drive unit is properly set up before installing it into the transaxle.
- Make sure that all electrical wiring to the solenoids and sensors **(Figure 43–34)** are connected and that all the harness clamps hold the wiring where it should.
- Air test the entire transmission **(Figure 43–35)** before installing the oil filter and oil pan.
- Install a new oil filter and pan gasket. Tighten the oil pan bolts to specifications.
- Always flush out the transmission cooling system before using a rebuilt or new transmission. The cooling system is a good place for debris to collect. Some manufacturers require replacement of the cooler rather than flushing it.

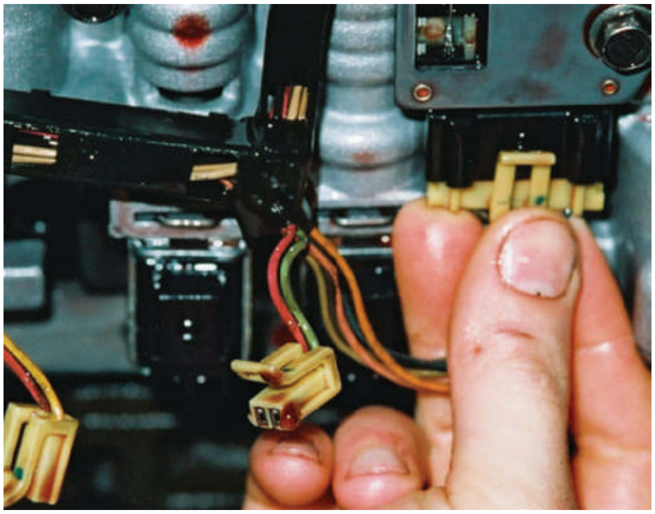

FIGURE 43–34 Make sure all of the electrical connectors are in place and are tight.

Installation

Transmission installation is generally the reverse of the removal procedure. A quick check of the following will greatly simplify your installation and reduce the chances of destroying something during installation.

- Make sure that the block alignment pins (dowels) are in their appropriate bores and are in good shape and that the alignment holes in the bell housing are not damaged.

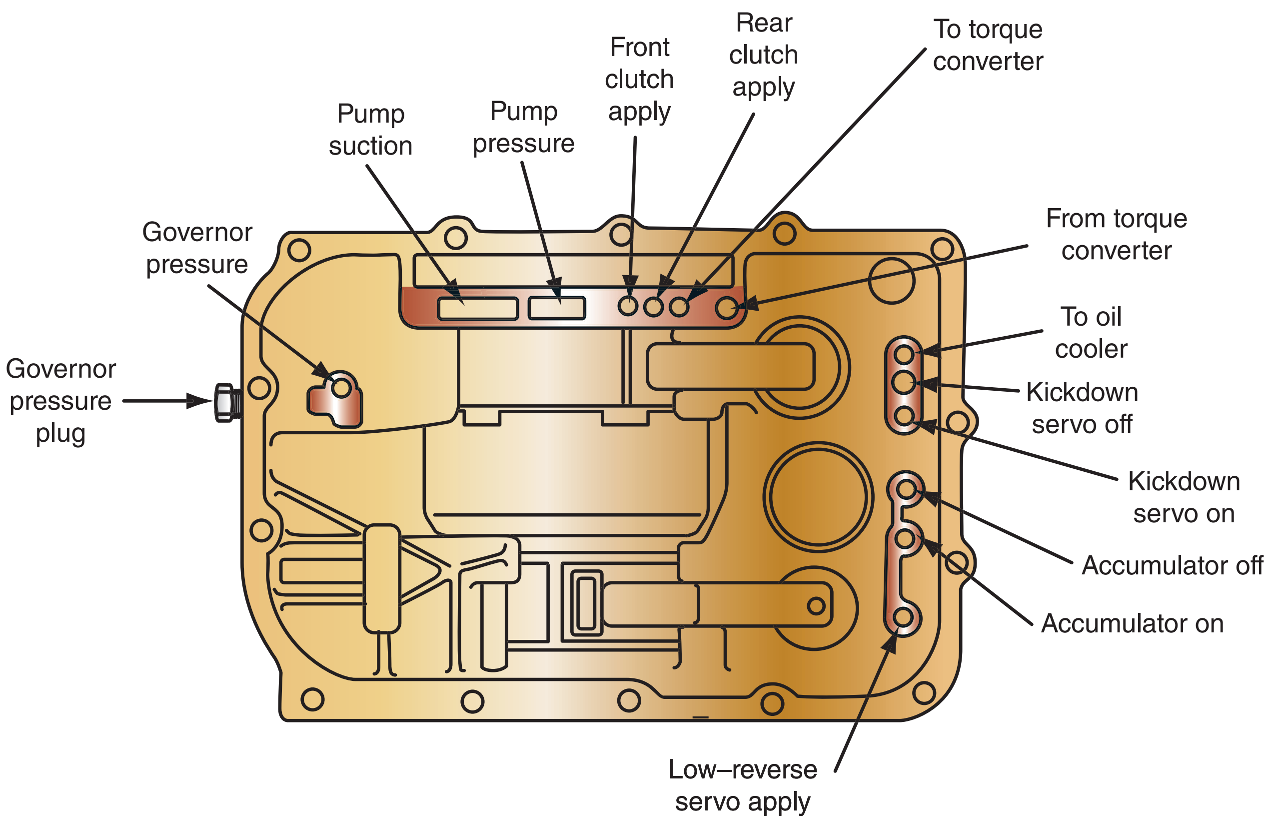

FIGURE 43–35 Air testing points in a typical transmission.

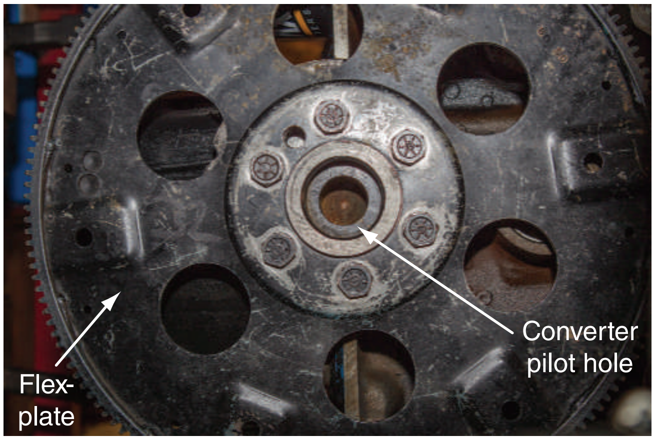

FIGURE 43–36 A pilot hole in a flex plate.

- Make sure that the pilot hole in the crankshaft is smooth and not out of round **(Figure 43–36)**. This will allow the converter to move in and out of the flexplate.
- Make sure that the pilot hub of the converter is smooth and that you cover it with a light coating of chassis lubricant to prevent chafing or rust.
- Make sure that the converter's drive hub is smooth and that you coat it with transgel or equivalent lubrication as specified.
- Secure all wiring harnesses out of the way to prevent their being pinched between the bell housing and engine block.
- Flush out the converter. It is recommended that clutch-type converters be replaced, because it is not possible to tell how much debris is in the unit.
- Always perform an end play check and check the overall height before reinstalling a torque converter or installing a fresh unit out of the box.
- Pour 1 quart of the recommended fluid into the converter before mounting the converter to the transmission. This will ensure that all parts in the converter have some lubrication before startup.

SHOP TALK

If the transmission is an EAT, check the service information before taking it on its initial road test. Most EATs require that a "Learning Procedure" be followed. This includes a variety of driving conditions. Because you need to road test and teach the transmission, you may as well do both at the same time.

A repaired transmission may require a shift adaptation relearn and a clutch learning procedure to be performed to make sure shift quality is correct. This can mean driving the vehicle with the transmission commanded to stay in certain gears using the manual gear selector or a scan tool and keeping the engine and transmission between specified speeds. Always refer to the manufacturer's service information for the correct procedures.

KEY TERM

Aeration

SUMMARY

- The ATF level should be checked at regular mileage and time intervals. Typically, when the fluid is checked, the vehicle should be level and running and the transmission should be at operating temperature.
- Both low fluid levels and high fluid levels can cause aeration of the fluid, which, in turn, can cause a number of transmission problems.
- Uncontaminated ATF is red in color and has no dark or metallic particles suspended in it.
- The fluid should be changed when the engine and transmission or transaxle are at normal operating temperatures. After draining the fluid, the pan should be inspected and the filter replaced.
- If ATF is leaking from the pump seal, the transmission must be removed from the vehicle so the seal can be replaced. Other worn or defective gaskets or seals can be replaced without removing the transmission. Case porosity may be repaired using an epoxy-type sealer.
- Slippage during shifting can indicate the need for band adjustment.
- Improper shift points can be caused by a malfunction in the governor or governor drive gear system or a misadjusted throttle linkage.
- The road test gives the technician the opportunity to check the transaxle or transmission operation for slipping, harshness, incorrect upshift speeds, and incorrect downshift.
- Accurate diagnosis depends on knowing what planetary controls are applied in a particular gear range.
- A pressure test checks hydraulic pressures in the transmission by using gauges attached to the transmission. Pressure readings reveal possible problems in the oil pump, governor, and throttle circuits.
- Proper adjustment of the gear selector or manual linkage is important to have the manual valve fluid inlet and outlets properly aligned in the valve body. If the manual valve does not align with the inlet and outlets, line pressure could be lost to an open circuit.

FOUR- AND ALL-WHEEL DRIVE

CHAPTER 44

OBJECTIVES

- Name the major components of a conventional four-wheel drive system.
- Name the components of a transfer case.
- State the difference between the transfer, open, and limited slip differentials.
- State the major purpose and operation of locking/unlocking hubs.
- Understand the difference between four- and all-wheel drive.
- Know the purpose of a viscous clutch in all-wheel drive.

With the popularity of 4WD and AWD SUVs, pickup trucks, and crossover vehicles **(Figure 44–1)**, the need for technicians who can diagnose and service four-wheel drive systems has increased drastically. Although all-wheel drive passenger cars are available, most prospective buyers for all-wheel and four-wheel drive vehicles are opting for cross-over vehicles, SUVs, and pickups.

Four-wheel drive (4WD) and **all-wheel drive (AWD)** systems can dramatically increase a vehicle's traction and handling ability in rain, snow, and off-road driving. Considering that the vehicle's only contact with the road is the small areas of the tires, driving and handling are improved when the work load is evenly spread out to four tires rather than two. However, it is important to note that most of these systems do not allow actual 4WD under most driving conditions. Driving all four wheels when traction is very low, such as on ice,

requires the ability to lock the differentials or wheel hubs. What most systems do is allow for torque to be routed to the both the front and rear axles, which improves traction.

The increased traction also makes it possible to apply greater amounts of energy through the drive system. Vehicles with 4WD and AWD can maintain control while transmitting levels of power that would cause two wheels to spin either on takeoff or while rounding a curve. The improved traction of 4WD and AWD systems allows the use of tires that are narrower than those used on similar 2WD vehicles. These narrow tires tend to cut through snow and water rather than hydroplane over them. Of course, wider and larger tires are often used in off-the-road adventures **(Figure 44–2)**.

Both 4WD and AWD systems add cost and weight to a vehicle. A typical AWD system adds approximately 170 pounds to a passenger car. The additional weight in larger 4WD trucks can be as much as 400 pounds or more. The systems also add to the initial cost of the vehicle. They also require special services and maintenance, and use more fuel, making the cost of operating a 4WD or AWD vehicle higher than operating a 2WD vehicle. For many, these disadvantages are heavily outweighed by the traction and performance these systems offer.

CUSTOMER CARE

Advise your customers that wear on 4WD systems is much greater than that on a 2WD transaxle or transmission, especially if drivers leave the four-wheel drive engaged on dry pavement. Some car makers warn that abuse of the system is not covered under the warranty.

Types of Drives

Because of the many names manufacturers give their drive systems, it is often difficult to clearly define the difference between 4WD and AWD. And both have the ability to send torque to all four wheels. However, today's AWD systems decide when to send torque to the front or rear axles, or both. 4WD systems can only lock the front and rear axles together, as a result each axle is always turning at the same speed. For the purposes of this text, the term four-wheel drive or 4WD is used to describe systems with a transfer case. Car-based systems that do not use a transfer case are discussed in the all-wheel drive (AWD) section. A **transfer case** splits the power from the transmission between the front and rear axles **(Figure 44–3)**. For clarity, the primary difference between an AWD and a 4WD is that the transfer case in a 4WD vehicle offers two speed ratios or gear ranges in four-wheel drive: typically called four-high and four-low. These systems are mostly found in pickups and large SUVs. An AWD vehicle does not offer this. AWD vehicles are usually

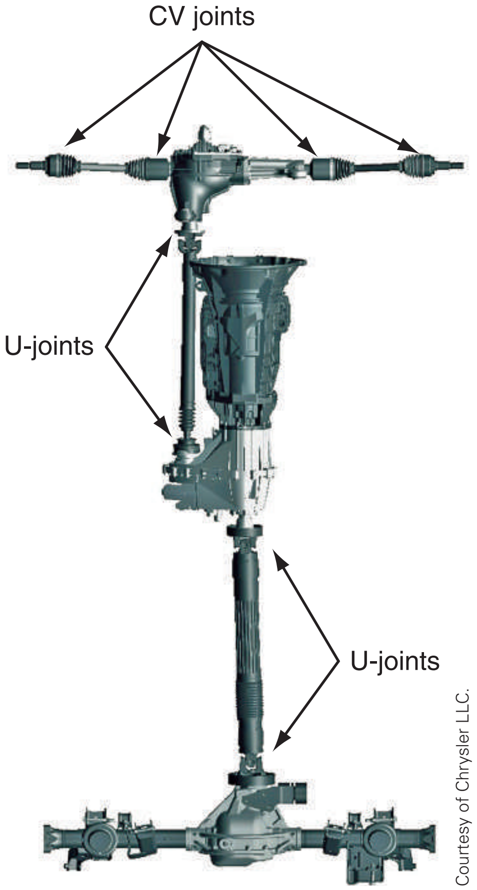

FIGURE 44–3 A typical arrangement of 4WD components.

smaller SUVs or passenger cars **(Figure 44–4)** and were developed for a front-wheel-drive based vehicle **(Figure 44–5)**.

FIGURE 44–4 A late-model AWD passenger car.

4WD vehicles do not drive all of the wheels all of the time. They use an open differential at the front and rear drive axles, and, in some cases, the center differential. An open differential splits the engine's torque output between the front and rear axles. The gear ratio of the front and rear axles can allow the axles to rotate at different speeds. However, the amount of torque transferred to the axles cannot be altered; therefore the torque will always move to the wheel or axle that has the least resistance. This means it is possible for a vehicle to become stuck with one wheel spinning while the others remain still. This happens when the axles and center differentials transmit torque to the wheels with the lowest traction.

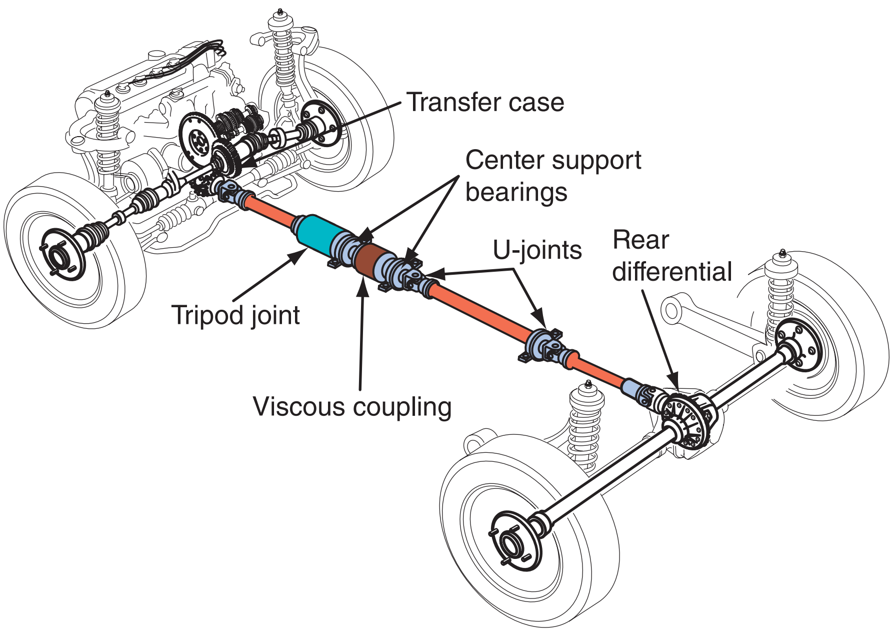

FIGURE 44–5 The layout of an AWD vehicle based on a FWD vehicle.

FIGURE 44–6 A locking hub from a 4WD truck.

Part-Time 4WD

Driving all four tires, all of the time, creates unwanted drag and binding in the drivetrain while driving on dry pavement. Limited slip (LSD) and locking differentials, locking hubs **(Figure 44–6)**, or couplings with torque management capability increase the ability to transfer and vary torque to all four wheels.

Part-time 4WD is designed to be used off-road. These systems provide a mechanical connection between the front and rear drive shafts when the transfer case is shifted into 4WD. Part-time systems are found on pickups and larger SUVs. These are RWD vehicles fitted with a two-speed transfer case and axle connects/disconnects. These 4WD systems operate in 2WD until the driver manually selects 4WD.

When 4WD is selected, more traction is available to allow the vehicle to either carry heavier loads and/or to travel in adverse terrain conditions. The system was designed just for those purposes and not for use on dry or smooth pavement. When operating in 4WD, the front and rear drive axles rotate with the same torque and there is no allowance for axle speed differences. When in 4WD and turning on dry surfaces, the tires scrub against the road surface since no difference in axle speed is available; as a result, the vehicle does not handle well. However, when the vehicle is cornering on a slippery surface, the tires easily skid or spin across the surface to allow for the required axle speed differences.

It must be kept in mind that the distances the tires must travel are different when the vehicle is making a turn **(Figure 44–7)**. The outside front wheel will travel further than the outside rear wheel and the result is called **driveline windup**. This is the main reason for new AWD transfer case designs using clutch packs or viscous couplings to permit full time use on dry pavement. Driveline windup can cause

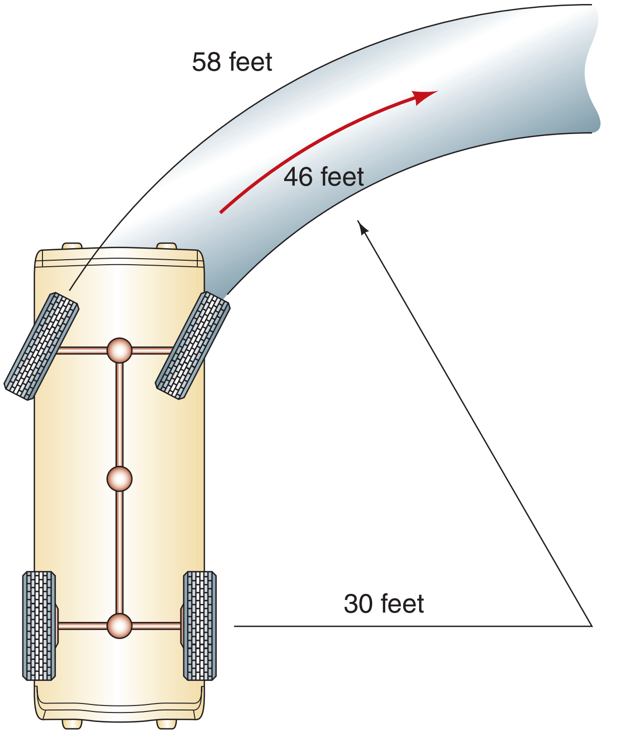

FIGURE 44–7 The distance the wheels travel while a vehicle is making a turn.

handling problems, particularly when rounding turns on dry pavement.

The drive shafts from the transfer case connect to differentials at the front and rear drive axles **(Figure 44–8)**. Universal joints are used to connect the drive shafts to the differential and the transfer

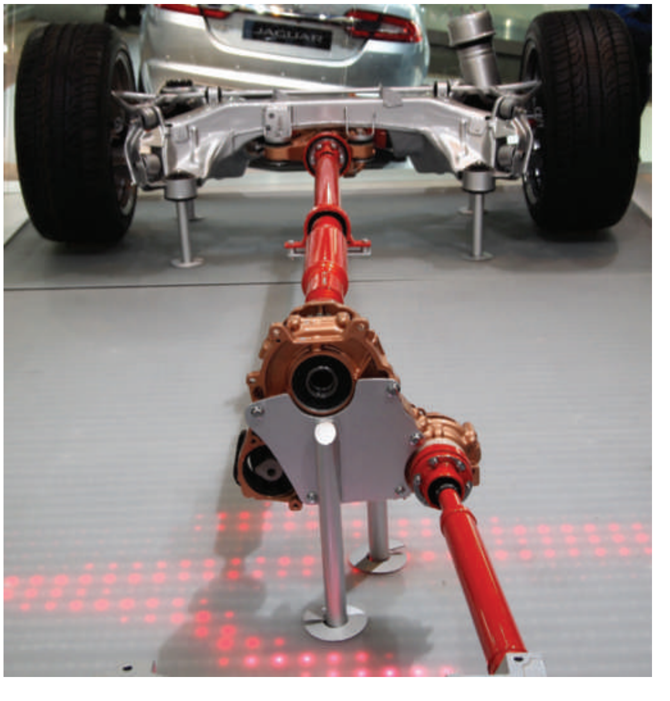

FIGURE 44–8 A transfer case and driveshafts.

case. The drive axles are either connected directly to the hub of the wheels or are connected to the hubs by U-joints. Universal joints are also normally used to connect the front axles to the wheel hubs on heavy-duty trucks **(Figure 44–9A)**. Light-duty vehicles generally use half shafts and CV joints in their front drive axle assembly **(Figure 44–9B)**.

Nearly all part-time 4WD systems have a transfer case that not only allows for 2WD or 4WD, but also offers two different speed ratios: high and low. This feature allows the driver to control how engine torque will be distributed to the drive wheels. The selector switch **(Figure 44–10)** or mechanical shifter **(Figure 44–11)** that controls the transfer case normally has 2WD, 4WD high, and 4WD low positions. The shift control either physically moves a gear in the transfer case or activates an electrically operated solenoid or clutch pack to send torque to the front axle. Nearly all newer vehicles use electronic 4WD controls, many of which also

provide for various modes of operation, such as in sand and snow **(Figure 44–12)**. Also, most mechanical shifters offer a neutral position that is used as a stopping point before 4WD low can be selected. Other

FIGURE 44-12 A terrain selector for a 4WD vehicle.

transfer cases are a single speed and only allow the driver to select between 2WD and 4WD modes.

When 2WD is selected, only the rear drive axle is engaged and this setting is used for all dry-road driving. Most vehicles use an open or limited-slip rear differential and some have the ability to lock the rear if needed. 4WD high transfers engine power to both axles, without affecting the amount of torque sent to the drive wheels. This gear selection provides 4WD traction on surfaces covered with ice or packed snow. 4WD low places the transfer case in a gear reduction configuration. The gear reduction may be 2:1, 4:1 or higher and provides great torque multiplication to the drive wheels. This high torque multiplication drastically decreases the speed of the vehicle. The sole purpose of this gear is to provide more traction force at the drive wheels to overcome rough terrain, including rocks, snow, gravel, or steep inclines.

Shifting

Some 4WD vehicles use a vacuum motor or mechanical linkage to move a splined sleeve to connect or disconnect the front drive axle **(Figure 44–13)**. With this system, locking hubs are not needed. When 2WD is selected, one axle is disconnected from the front differential. As a result, all engine torque moves to the side of the differential with the axle disconnected. This is due to normal differential action. When the vehicle is shifted into 4WD, the shift collar connects the two sections of the axle shaft together.

Other axle disconnects are operated electrically. An electric motor can be used to connect and disconnect the axle **(Figure 44–14)**. This system allows for a smooth transition from two- to four-wheel drive. General Motors uses a system whereby selecting 4WD on the selector switch energizes a heating element in the axle disconnect. The heating element heats a gas causing the plunger to operate the shift mechanism.

Most late-model vehicles with a mechanical or electronic 4WD control allow the driver to switch between 2WD and 4WD while the vehicle is moving or "on the fly." These systems work with the vehicle's PCM and integrated wheel ends (IWE) solenoids. The driver can typically switch between 2WD and 4WD at speeds up to 55 mph (88 km/h). However, switching from 4WD high to 4WD low requires that the vehicle be traveling at less than 3 mph (5 km/h) with the brake pedal pressed and the transmission in neutral. The transfer case is fitted with an electromagnetic clutch **(Figure 44–15)** that is used to synchronize the front driveline with the transmission's output. When

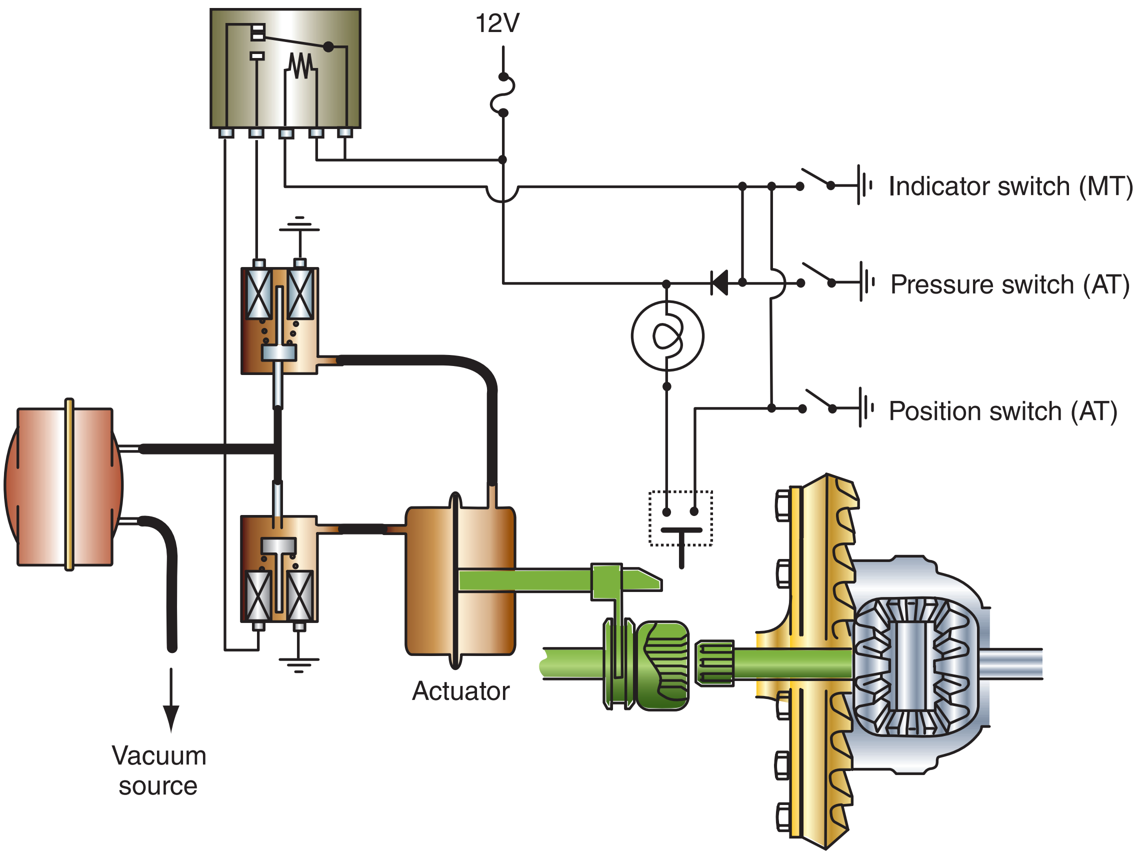

FIGURE 44–13 A vacuum operated axle disconnect system.

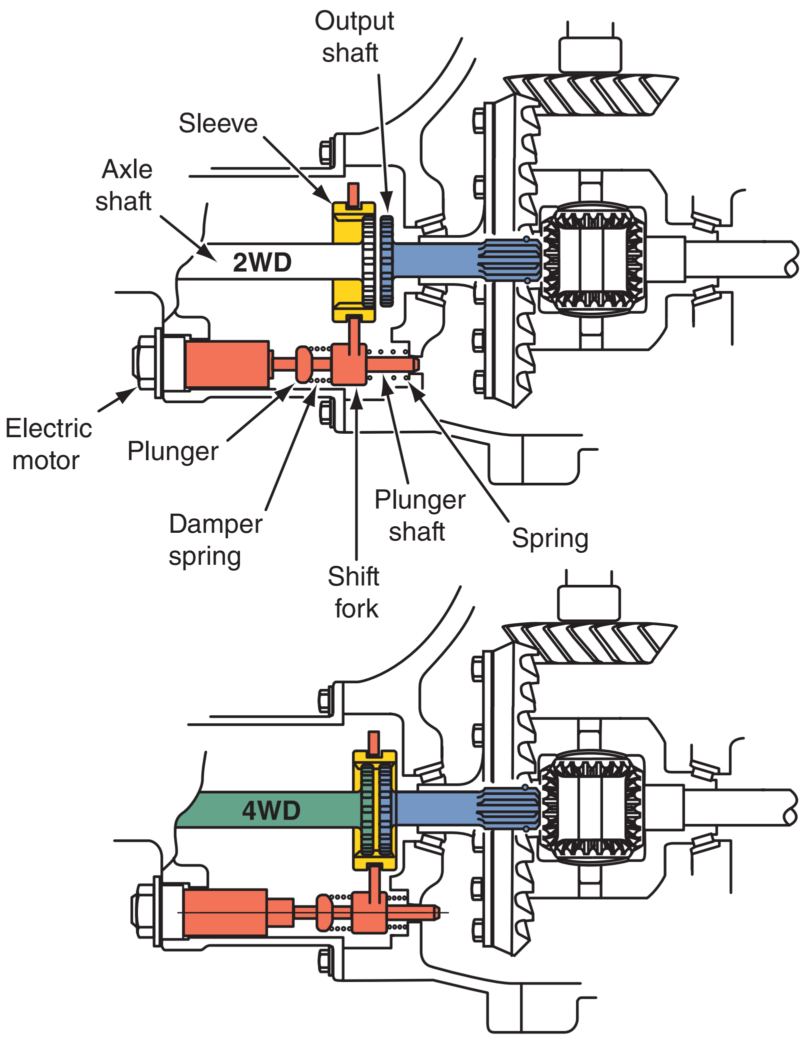

FIGURE 44–14 An electric motor disconnects the axles in this system.

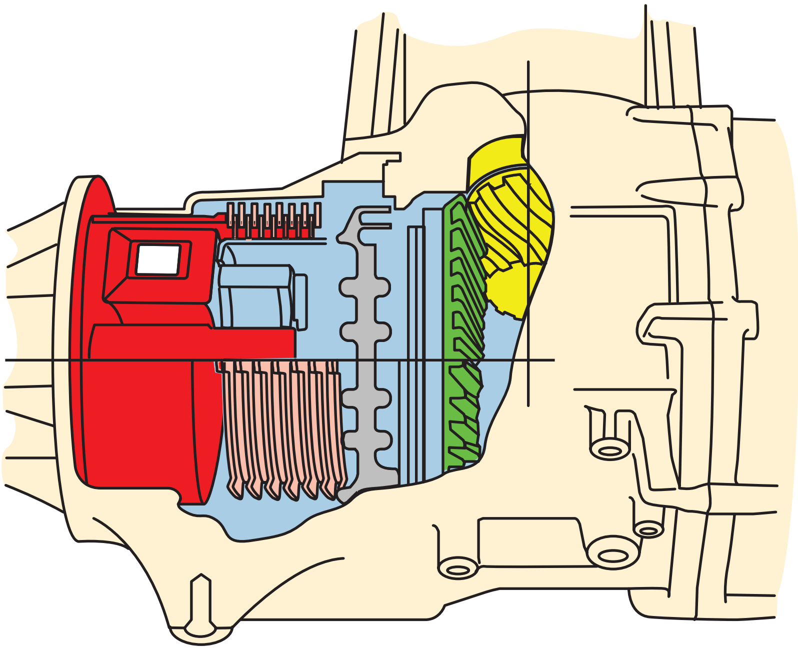

FIGURE 44–15 The clutch assembly in this transfer case is used to synchronize the front driveline with the transmission's output.

the manual shift lever is moved into 4WD, the electromagnetic clutch is energized. This causes a shifting collar to engage the transfer case's main shaft hub to the drive sprocket for the front drive shaft. The front axle integrated wheel ends (IWEs) are engaged, then the electromagnetic clutch is disengaged. In electronic shifter transfer cases, the clutch ultimately controls a shift motor.

FWD-Based Systems Some FWD vehicles fitted for 4WD use a compact transfer case bolted to the transaxle. A drive shaft then carries the power to the rear differential. The driver can switch from 2WD to 4WD by pressing a switch that activates a solenoid vacuum valve or electric motor.

All-Wheel Drive

All-wheel drive cars and trucks differ from heavier-duty 4WD trucks and SUVs in several other ways. First, there is no separate transfer case; any gearing needed to transfer power to the rear driveline is usually contained in the transaxle housing or small bolt-on extension housing **(Figure 44–16)**. The reason some cars are equipped with AWD is to improve their handling, although the ability to drive all four wheels does help during inclement weather conditions. Other vehicles use AWD to increase handling performance by applying torque to each wheel based on driving conditions.

An AWD system may transfer constant power to the front and rear axles or power may only transfer under slippery conditions. AWD systems usually incorporate a center or interaxle differential between the front and rear output shafts **(Figure 44–17)**.

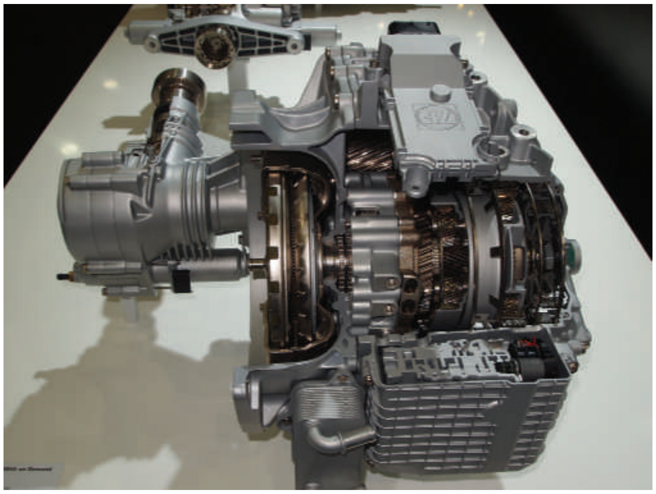

FIGURE 44–16 A nine-speed transaxle with bolt-on transfer case to provide AWD.

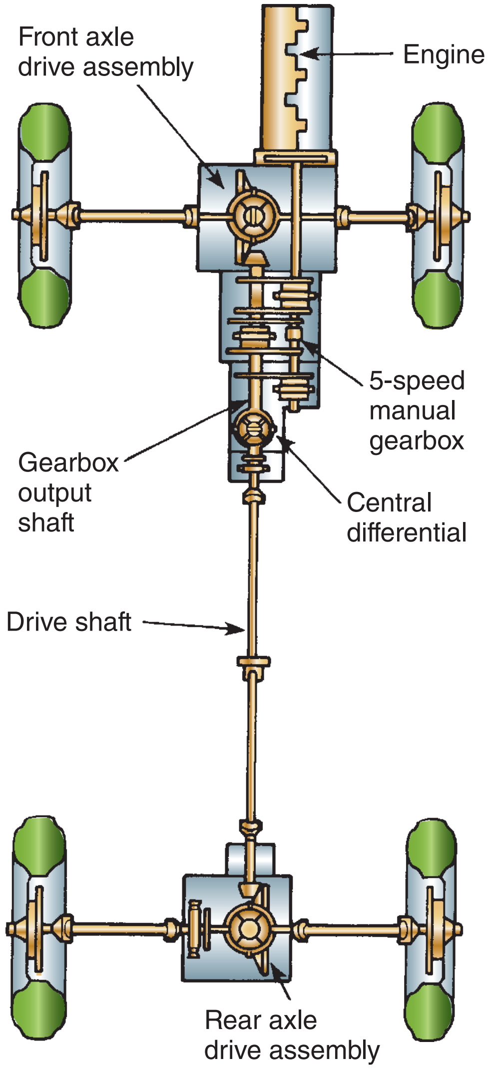

FIGURE 44–17 The placement of a center differential for a full-time 4WD system.

Full-time AWD can also be called "anytime 4WD" or AWD, although this is not entirely a correct designation. Like part-time 4WD, AWD provides a vehicle with more traction but it makes it more practical for everyday use, as it can be used full time on all surfaces including dry pavement. These systems cannot be selected out of AWD and output torque is spread equally to the drive wheels if the road conditions permit this. To prevent tire scrub during cornering, the system may have an additional differential incorporated into the transfer case or between the front and rear drive axles. The extra differential, called a center or interaxle differential, allows for a speed difference between the front and rear axles.

Full-Time AWD

Full-time AWD is similar to 4WD, in that it powers all four wheels at all times. However that 4 low setting

is not available. Since it does not have this low gear, vehicles with AWD are not designed for serious off-road excursions, but can be used on all other surfaces, including dry pavement.

Most passenger cars and smaller SUVs equipped with AWD are based on FWD designs. These modified FWD systems consist of a transaxle and differential to drive the front wheels, plus some type of mechanism for connecting the transaxle to a rear driveline. They do not have a separate transfer case; rather, a viscous clutch, center differential **(Figure 44–18)**, or electromagnetic transfer clutch is used to transfer power from the transaxle to a rear driveline and rear axle assembly.

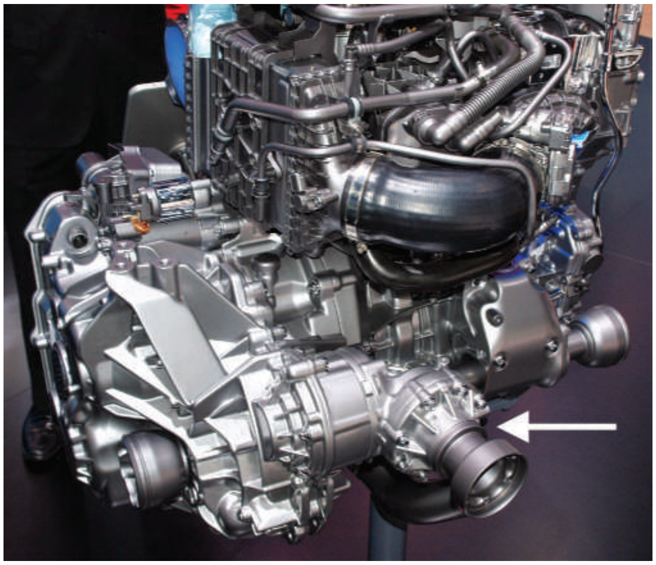

FIGURE 44-18 A center differential located at the transaxle.

Depending on the vehicle, all torque may be sent to the front wheels, but that can change with changing operating conditions. When the vehicle is moving straight on a level road, each wheel receives the same amount of torque. During a turn, the front wheels receive less torque; this prevents wheel slip. If one of the front wheels begins to slip, more torque is sent to the rear wheels. Other systems send a percentage of the torque to the front wheels and some to the rear all of the time. Many of these newer systems dynamically change the front/rear torque split and use brake-based torque vectoring to provide 4WD-like performance from the drivetrain.

These systems rely on a single-speed transfer case added to the transaxle and/or an interaxle differential to split power between the front and rear axles. The system responds to inputs from a variety of sensors. The primary input is wheel slip which is monitored by wheel-speed sensors connected to the CAN bus. When the system detects wheel slippage, the control module fully activates the clutch to send more torque to the front or rear wheels **(Figure 44–19)**. The control module monitors these inputs and adjusts the torque bias at the center, front, and/or rear differentials.

Automatic AWD

Vehicles equipped with automatic AWD may operate in 2WD most of the time and operate in AWD for only brief periods of time. Under normal conditions one axle gets 100 percent of the torque, and power to

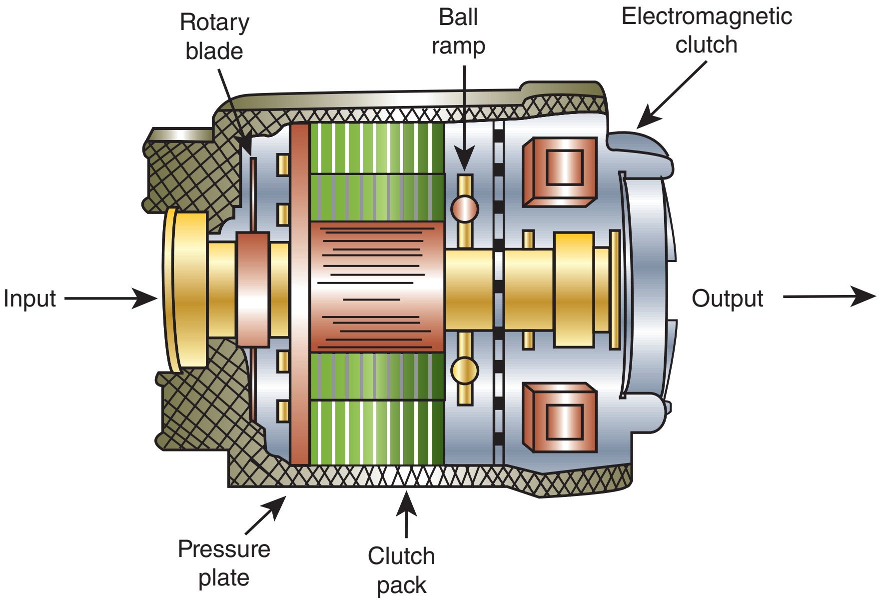

FIGURE 44-19 An electronically controlled clutch.

four wheels only occurs when the conditions make it desirable or necessary.

The PCM constantly monitors the speed of each wheel **(Figure 44–20)**. When an axle experiences some slippage, the control unit splits the power, accordingly, to the other axle. This power split can be accomplished hydraulically, mechanically, or electrically, depending on the system. As soon as the axle is no longer slipping and all four wheels are rotating at the same speed, all torque is sent to that axle.

Normally, to split the power between axles, a multiple disc clutch is used. This clutch serves as an interaxle differential and permits a speed difference between the front and rear drive axles. Sensors monitor front- and rear-axle speeds, engine speed, and load on the engine and driveline **(Figure 44–21)**. An electronic traction control unit (TCU) receives information from the sensors and controls a solenoid that operates on a duty cycle to control the fluid flow that engages the transfer clutch. The duty solenoid

pulses, cycling on and off very rapidly, which develops a controlled slip condition. As a result, the transfer clutch operates like an interaxle differential and allows for a power split from 95 percent FWD and 5 percent RWD to 50 percent FWD and 50 percent RWD. This power split takes place so rapidly that the driver is unaware of the traction problem.

AWD Hybrids

On Toyota and Lexus hybrid SUVs, the front transaxle assembly has been modified to include a speed reduction unit. This unit is a planetary gearset coupled to the power-split planetary gearset. In addition, at the rear axle, an additional motor/generator (MGR) is placed in its own transaxle assembly to rotate the rear drive wheels. Unlike conventional 4WD vehicles, there is no physical connection between the front and rear axles **(Figure 44–22)**. The aluminum housing of the rear transaxle contains the motor/generator (MGR), a counter drive gear, counter driven gear, and a differential. The unit has three shafts: MGR and the counter drive gear are located on the main shaft (MGR drives the counter drive gear), the counter driven gear and the differential drive pinion gear are located on the second shaft, and the third shaft holds the differential.

Unlike the 4WD Toyotas, the Ford Escape hybrid does not have a separate motor to drive the rear wheels. Rather, these wheels are driven in a conventional way with a transfer case, rear drive shaft, and a rear axle assembly. This AWD system is fully automatic and has a computer-controlled clutch that engages the rear axle when traction and power at the rear are needed. The system relies on inputs from sensors located at each wheel and the accelerator pedal. The system calculates how much torque should be sent to the rear wheels. By monitoring these inputs, the control unit can predict and react to wheel slippage. It also can make adjustments to torque distribution when the vehicle is making a tight turn; this eliminates any driveline shudder that can occur when a 4WD vehicle is making a turn.

4WD Drivelines

The heart of conventional 4WD vehicles is the transfer case, which may be integrated into the transmission **(Figure 44–23)** or mounted to the back of the transmission **(Figure 44–24)**. A chain or gear drive within the case receives the power from the

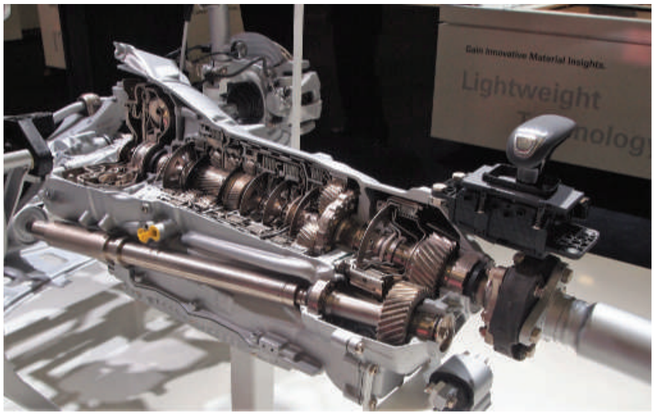

FIGURE 44–23 The transfer case is integrated with the transmission.

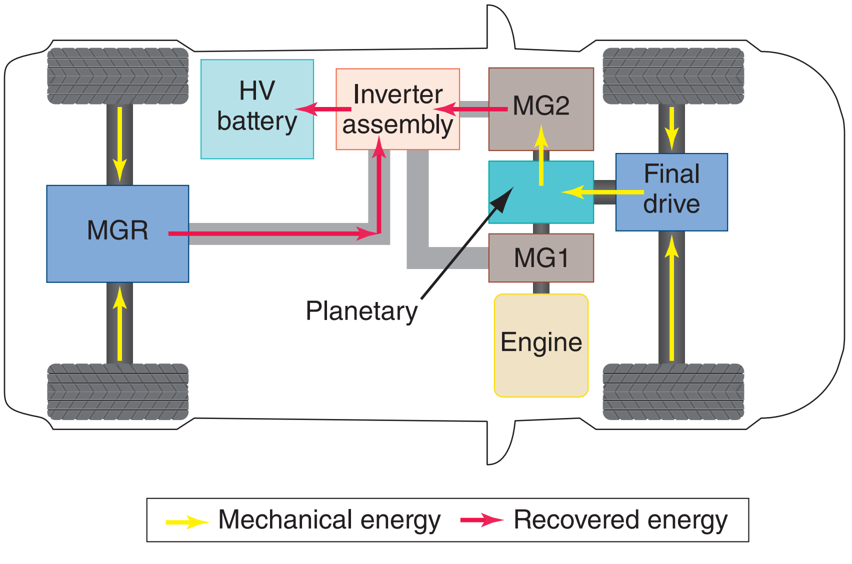

FIGURE 44–22 The basic layout for a hybrid vehicle equipped with an additional motor to drive the rear wheels.

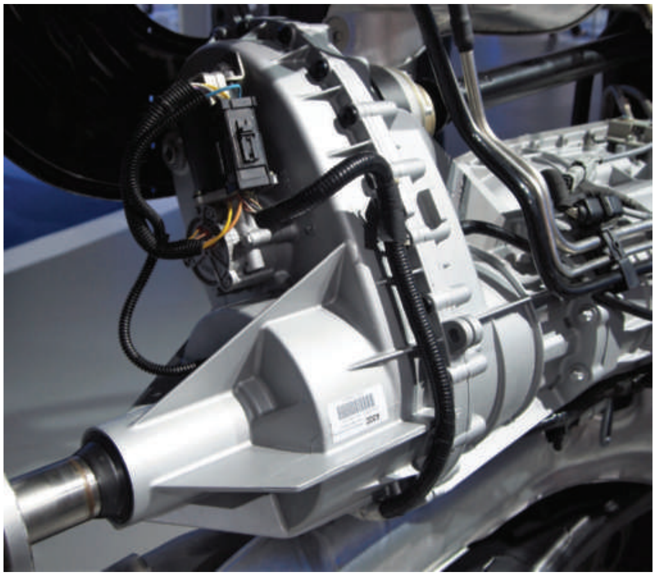

FIGURE 44–24 The transfer case is bolted to the rear of this transmission.

transmission and transfers it to the front and rear axles through two separate drive shafts.

The driveline from the transfer case shafts run to differentials at the front and rear axles. As on two-wheel drive vehicles, these axle differentials are used to compensate for road and driving conditions by adjusting the rpm to opposing wheels. For example, the outer wheel must roll faster than the inner wheel during a turn because it has more ground to cover. To permit this action, the differential cuts back the power delivered to the inner wheel and boosts the amount of power delivered to the outer wheel.

U-joints are used to couple the driveline shafts with the differentials and transfer cases on all these vehicles. U-joints can also be used on some vehicles to connect the rear axle and wheels. Normally, however, rear axles are simply bolted to the wheel hubs.

The coupling between front wheels and axles is normally done with U-joints or CV (constant velocity) joints. Generally, half axles or half shafts with CV joints are found on AWD passenger cars. They can also be found on a number of passenger vans and on mini pickups and trucks.

To provide independent front suspension, some vehicles have one half shaft and one solid axle for the front drive axle **(Figure 44–25)**. The half shaft is able to move independently of the solid axle, thereby giving the vehicle the ride characteristics desired from an independent front suspension.

Transfer Case

In a 4WD vehicle, as mentioned earlier, the transfer case delivers power to both the front and rear assemblies. Two drive shafts normally operate from the transfer case, one to each drive axle.

A transfer case **(Figure 44–26)** is constructed much like a transmission. Some transfer cases rely on a chain and sprockets and others use gears to rotate the driveshaft to the front or rear axle.

It uses shift forks to select the operating mode, plus splines, gears, shims, bearings, and other components found in manual and automatic transmissions. The outer case of the unit is made of cast iron, magnesium, or aluminum. It is filled with lubricant (oil) that cuts friction on all moving parts.

Power Transfer (Takeoff) Units

On AWD systems adapted from front-wheel drive systems, a separate front differential and driveline are not needed. The front wheels are driven by the transaxle differential of the base model. A power transfer (takeoff) unit (PTU) is added to the transaxle to transmit power to the rear wheels in four-wheel drive. This takeoff gearing is housed in or bolted to the transaxle housing **(Figure 44–26)**. It is simply a gearset, driven by the transaxle's final drive, that transfers the output torque at a 90-degree angle and rotates the rear driveshaft at the same speed as the front wheels.

Jeep Compass The current AWD Jeep Compass has electronic controls that decide when to engage the rear axle, via the PTU, by monitoring the outside temperature, wheel speed changes, windshield wiper use, and other inputs. On warm and dry days, the PTU, the rear ring and pinion, and the rear drive shaft are totally disconnected from the engine. When conditions indicate that there is a possibility of wheel spin, a clutch in the rear differential and a toothed dog clutch in the PTU turn on, this sends torque to the rear.

Locking Hubs

A transfer case can only disconnect power to one of the driveshafts, either to the front or rear. Although the driveshafts are disconnected from the engine,

CUSTOMER CARE

It is very important to remind your customers that the fluid level in a transfer case must be checked at recommended time intervals. (Check the owner's manual). Remind them to make sure only the correct fluid is used.

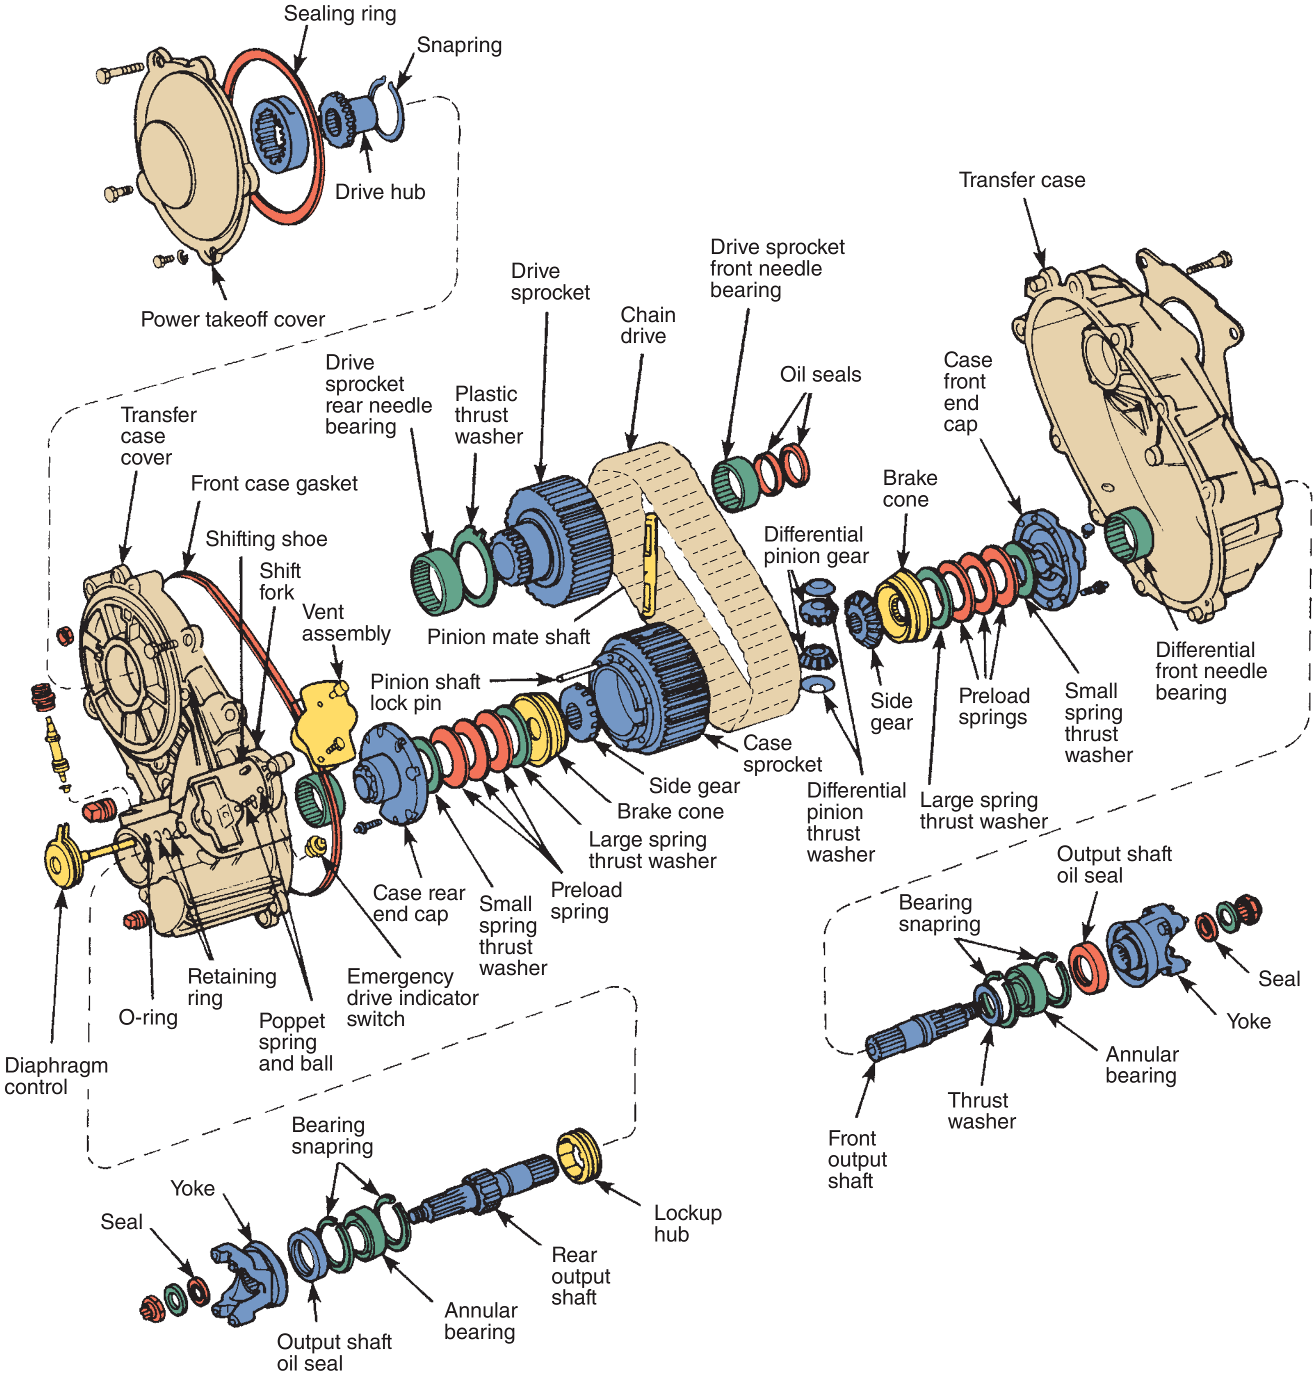

FIGURE 44–25 This transfer case receives the output from the transmission via a chain drive before power is sent to the rear wheels.

the wheels of the disconnected axle will still drive the driveshaft and the gears and axle shafts. This causes unnecessary wear on the system and wastes fuel. Some 4WD vehicles are equipped with wheel hubs that engage or disengage the axle shafts from the engine's power. These hubs can be manually operated gear and ratchet assemblies or automatically switched to lock or unlock the axles power flow.

On some 4WD vehicles, the front axles are engaged by locking wheel hubs. The hubs are designed to stop the rotation of the front axles and differential when 4WD is not selected. **Locking hubs** can be either manual or automatic. Newer systems have automatic hubs that engage when the driver switches into 4WD. Older vehicles had manual hubs that require the driver to turn a knob on the

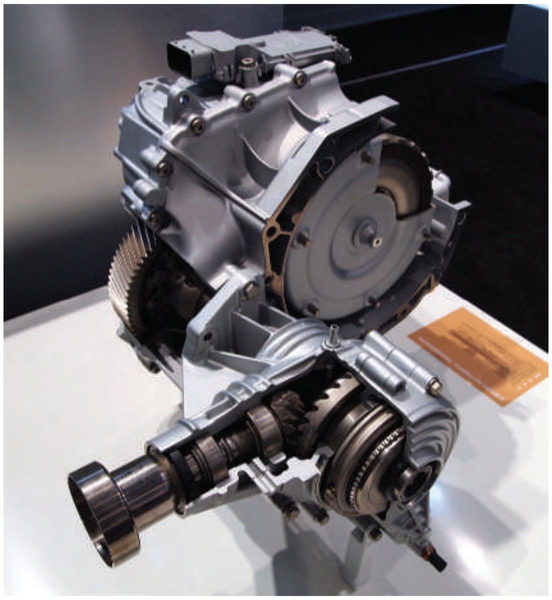

FIGURE 44–26 A PTU bolted to a transaxle.

front wheels. These hubs connect the front wheels to the front drive axles when they are in the locked position.

Manual locking hubs require that a lever or knob be turned by hand to the 2WD or 4WD position **(Figure 44–27)**. Automatic locking hubs can be locked by shifting to 4WD and moving forward slowly **(Figure 44–28)**. They are unlocked by slowly backing up the vehicle. On certain late-model 4WD systems, a front axle lock is used in place of individual locking hubs.

A locking hub is a type of clutch that engages or disengages the outer ends of the front axle shafts from the wheel hub. When the hub is in the locked position, the ring of the clutch is set onto the splines of the axle shaft. When the hub is in the unlocked position, spring pressure forces the clutch ring away from the axle shaft, thereby disconnecting the wheel hub and the axle.

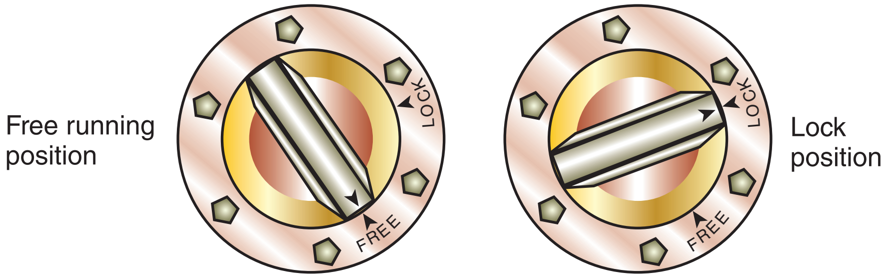

FIGURE 44–27 The knob positions for a manual locking hub.

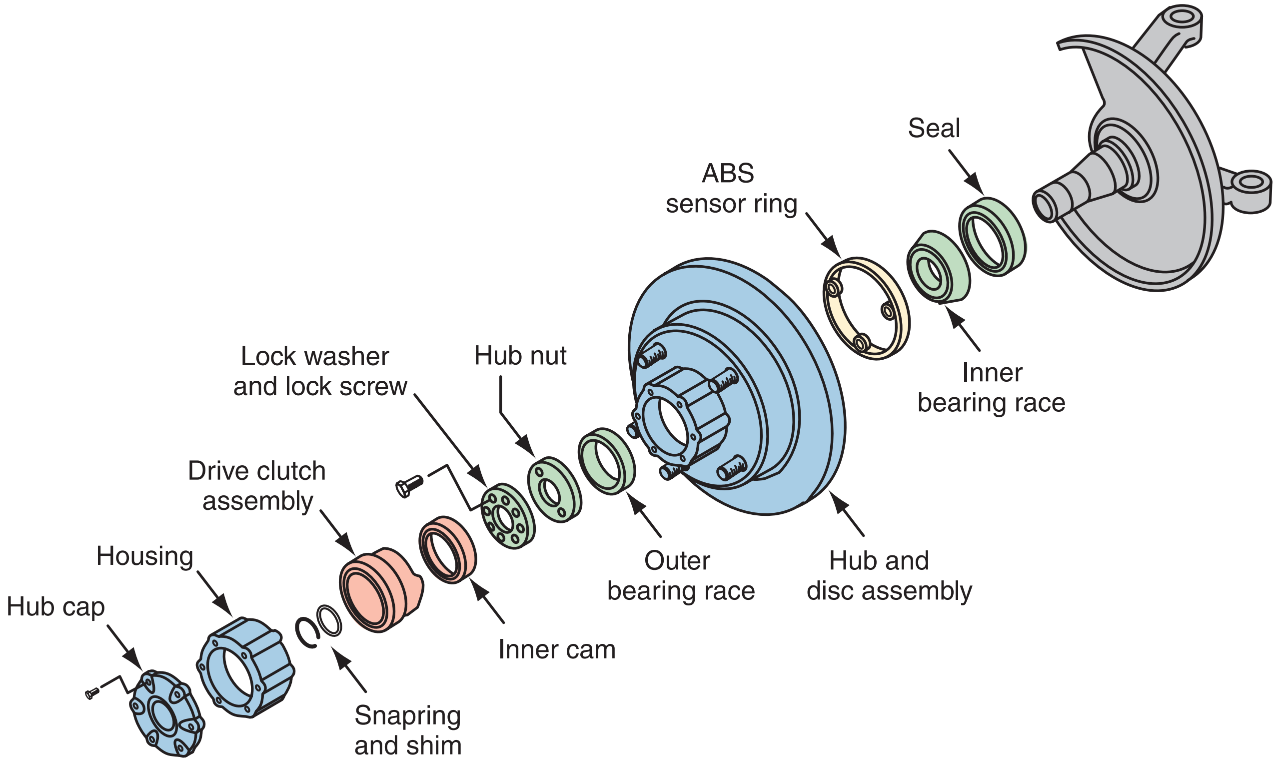

FIGURE 44–28 The parts of an automatic locking front hub.

Although automatic hubs are more convenient for the driver, they do have a disadvantage. Many self-locking hub designs are unlocked when the vehicle is moved in reverse. Therefore, if the vehicle is stuck and needs to back out of the trouble spot, only RWD will be available to move it. Other automatic hubs unlock immediately when 4WD is disengaged without the need to back up. On these systems, the hubs are automatically locked, regardless of the direction the vehicle is moving.

Locking hubs are not needed with full-time AWD. The wheels and hubs are always engaged with the axle shafts. The interaxle differential or transfer case prevents damage and undue wear of the parts of the powertrain.

Interaxle (Center) Differentials

AWD systems require a device that allows the front and rear axles to rotate at different speeds. These units work to eliminate driveline windup. The most common setup has an **interaxle (center) differential (Figure 44–29)**. The front and rear drivelines are connected by a drive shaft to the center differential. Just as a drive axle differential allows for different left and right drive axle shaft speeds, the center differential allows for different front and rear driveline shaft speeds **(Figure 44–30)**.

While the interaxle differential solves the problem of driveline windup during turns, it also lowers performance in poor traction conditions. This is because the interaxle differential will tend to deliver more power to the wheels with the least traction. The result is increased slippage, which is the exact opposite of what is desired.

To counteract this problem, some interaxle differentials are designed much like a limited slip differential. They use a multiple-disc clutch pack to maintain a predetermined amount of torque transfer before the differential action begins to take effect **(Figure 44–31)**.

Electromagnetic systems use an electromagnetic coil to engage a multiplate clutch to transfer torque to the rear axle. If the front wheels are turning faster than the rear, the PCM applies the clutch to drive the rear wheels. Some systems use a Torsen or Haldex unit in the center differential. A Torsen or *tor*que *sen*sing unit is a mechanical differential capable of transferring power from a wheel with little or no traction to the other wheel that has traction. Other systems such as the one shown in Figure 44–22 use a cone braking system rather than a clutch pack, but the end result is the same. Power is supplied to both axles regardless of the traction encountered.

Some systems also give the driver the option of locking the interaxle differential in certain operating

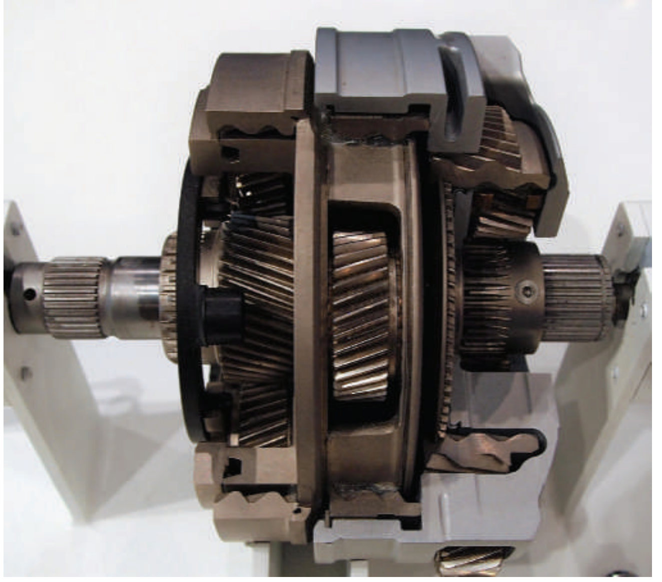

FIGURE 44–29 A center differential.

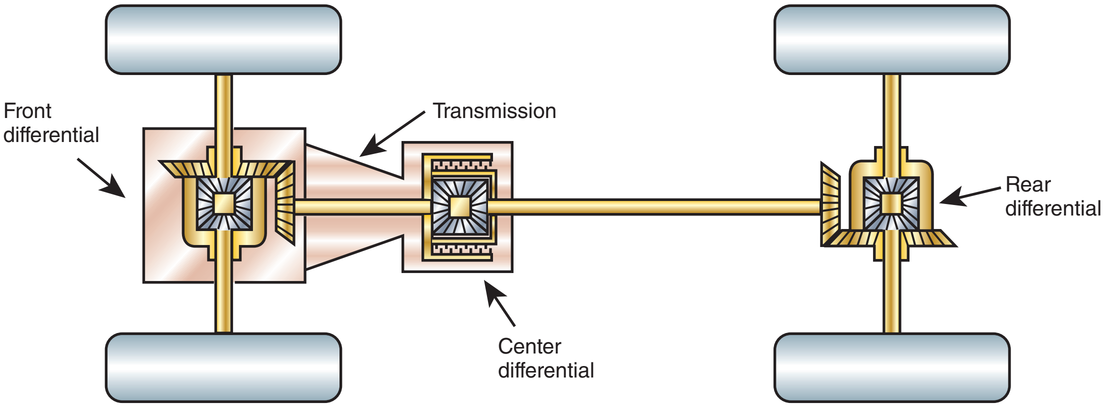

FIGURE 44–30 The center differential allows for different front and rear speeds.

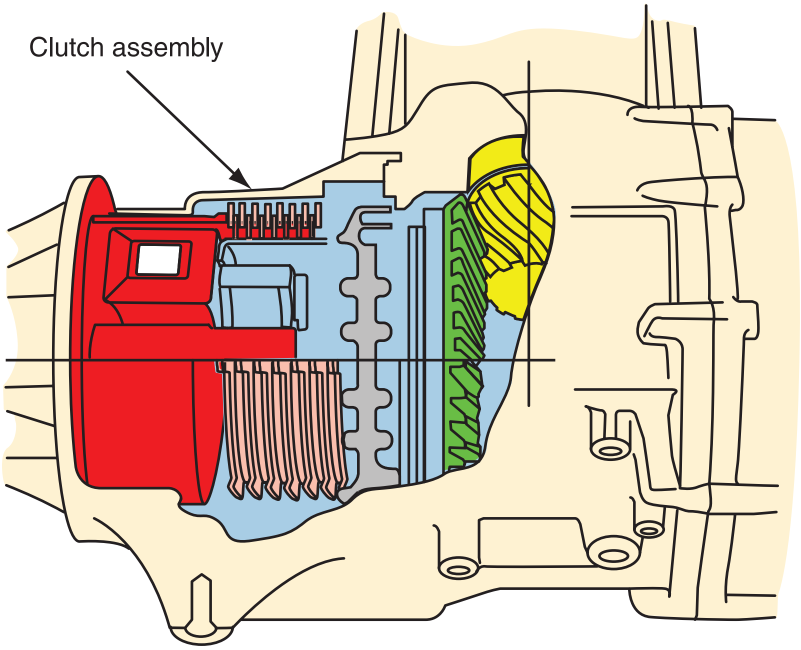

FIGURE 44–31 A mechanical clutch assembly for a center differential.

modes **(Figure 44–32)**. This eliminates the differential action altogether. However, the differential should only be locked while driving in slippery conditions and can only be activated at low speeds.

FIGURE 44–32 The center differential can be controlled by these selectors.

Audi's Quattro System

Early Audi Quattro systems relied on Torsen or viscous clutch center differentials, but newer models use an electronically controlled multiple-disc clutch to route the engine's torque. This new system is called Quattro with Ultra. It is capable of idling the rear axle's ring and pinion gears and driveshaft. Two clutches on the transmission's output shaft and a toothed dog clutch in the rear differential open to disengage the drag-inducing parts, enabling better fuel economy. Several environmental factors are considered by the ECM that controls the operation of this differential, which include outside temperature, yaw rate, steering angle, throttle position, and wheel speed.

Helical Center Differential

Helical center differentials, commonly called Torsen units, use tuned planetary gears with teeth cut in a helical spiral pattern that bind up or push against friction discs to limit wheel spin and alter torque distribution. They increase the torque from the engine to create more friction to enhance the locking action. The locking action is determined by the angle at which the gears are cut, steeper angles produce more locking force. When used as a center

differential, helical limited slip differentials are often designed to offer an unequal torque bias—an effect determined by the ratio between the gears to drive the front and rear axles.

Viscous Clutch

Some systems use a viscous clutch in the transfer case, outside the transfer case **(Figure 44–33)**, or as a separate unit to split the power to the front and rear axles. A **viscous clutch** is used to drive the axle with low tractive effort, taking the place of the interaxle differential. In existence for several years, the viscous clutch is installed to improve mobility under difficult driving conditions. Viscous clutches operate automatically while constantly transmitting power to the axle assembly as soon as it becomes necessary to improve driving wheel traction. This action is also known as biasing driving torque to the axle with tractive effort. The viscous clutch assembly is designed similarly to a multiple-disc clutch with alternating driven and driving plates **(Figure 44–34)**. The coupling functions as a speed sensitive limited slip unit.

The viscous clutch pack fits inside a drum that is completely sealed. The clutch pack is made up of alternating steel and friction plates. One set of steel plates is splined internally to the clutch assembly hub. The second set of clutch plates is splined externally to the clutch drum. The clutch housing is filled with a small amount of air and special silicone fluid with the purpose of transmitting force from the driving plates to the driven plates.

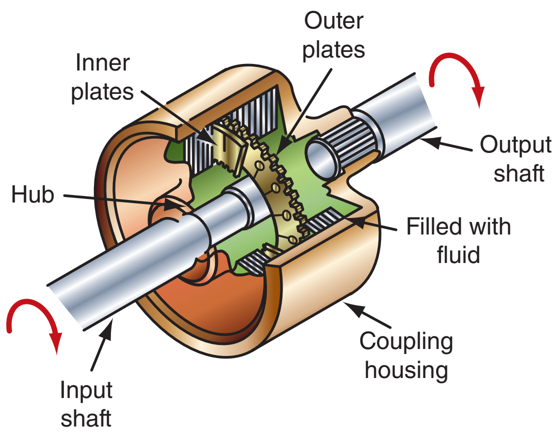

FIGURE 44–34 Inside a typical viscous clutch assembly.

When the front and rear differentials are at the same speed, the clutch pack rotates slowly and little or no torque is transferred through the coupling. As the speed difference increases, so does the amount of transferred torque. When a difference in speed of 8 percent exists between the input shaft driven by the driving axle with tractive effort, the clutch plates begin shearing (cutting) the special silicone fluid. The shearing action causes heat to build within the housing very rapidly, which results in the silicone fluid stiffening. The stiffening action causes a locking action between the clutch plates to take place within approximately 0.10 second. A locking action results from the stiff silicone fluid, making it very hard for the plates to shear. The stiff silicone fluid transfers power from the driving to the driven plates.

The driving shaft is then connected to the driven shaft through the clutch plates and stiff silicone fluid.

During normal driving, the coupling allows enough slippage for the front and rear wheels to travel at different speeds while turning corners. The viscous clutch has a self-regulating control. When the clutch assembly locks up, there is very little, if any, relative movement between the clutch plates. Because there is little relative movement, silicone fluid temperature drops, which reduces pressure within the clutch housing. As speed fluctuates between the driving and driven members, heat increases, causing the silicone fluid to stiffen. Speed differences between the driving and driven members regulate the amount of slip in a viscous clutch driveline. The viscous clutch takes the place of the interaxle differential, biasing driving torque to the normally undriven axle during difficult driving conditions.

Haldex Clutch

Some AWD vehicles are equipped with a **Haldex clutch (Figure 44–35)**, which serves as a center differential. This clutch unit distributes the drive force variably between two axles.

The Haldex unit has three main parts: the hydraulic pump driven by the slip between the axles or wheels, a wet multidisc clutch, and an electronically controlled valve. The unit is much like a hydraulic pump in which the housing and a piston are connected to one shaft and a piston actuator connected to the other **(Figure 44–36)**.

When a front wheel slips, the input shaft to the Haldex unit spins faster than its output shaft. This causes the pump to immediately generate oil flow. The oil flow and pressure engages the multidisc clutch to send power to the rear wheels. This happens extremely quickly because an electric pump and accumulator keep the circuit primed.

The oil from the pump flows to the clutch's piston to compress the clutch pack. The oil returns to the reservoir through a controllable valve, which adjusts the oil pressure and the force on the clutch pack. An electronic control module controls the valve.

In high slip conditions, a high pressure is delivered to the clutch pack. In tight curves or at high speeds, a much lower pressure is provided. When there is no difference in speed between the front and rear axles, the pump does not supply pressure to the clutch pack.

Volkswagen 4MOTION The Volkswagen 4MOTION AWD system uses a Haldex coupling as a center differential. The coupling is mounted in front and is part of the rear axle housing. The input shaft of the Haldex center differential is driven by a drive shaft from the transaxle. In a Haldex, the input shaft is totally separated from the output shaft, which is

connected to the rear final drive gears. Therefore, power is only sent to the rear wheels when the Haldex clutch is engaged.

The Haldex unit is controlled by a PCM that receives inputs from a variety of sensors. This means the system can respond to other driving conditions and not just wheel slip. When there is no slip, understeer, or oversteer, the vehicle operates as a 2WD vehicle. It only distributes power to the rear axle when it is needed.

On-Demand Systems

Many late model SUVs and crossovers are equipped with "on-demand" AWD systems. These systems engage the front and rear axles on an as needed basis. They can also adjust the torque applied to the inner and outer wheel. There are many different designs of on-demand systems; most rely on a center differential to control the flow of torque. Some use an electric motor to power the front wheels and do not need a center differential. Others, such as the Toyota RAV4 Hybrid, have a motor that powers the rear wheels. The following are a few of the basic systems found on today's vehicles.

On-Demand Coupling On-demand systems primarily drive only one axle until the coupling engages the opposite side axle. It will gradually engage the axle as needed. Most of these systems rely on clutch packs or a tooth coupling called a dog gear. A clutch pack coupling increases the torque routed to the opposite axle by increasing the clamping force on the friction discs. The systems return to 2WD when there is no need for AWD. On-demand coupling systems are desirable because they can be programed to send torque to the opposite axle before it is actually need. Of course this action is based on the inputs from a variety of sensors.

On-Demand Twin Rear-Axle Couplings These systems are based on earlier systems that have a dedicated clutch for the left and right rear axles. The rear drive axle assembly has ring and pinion gears but does not have differential gearing. When the clutches are fully engaged, the system works like a typical 4WD system. With this system, torque-vectoring is easily achieved by changing one axle ratio. The Ford Focus RS uses this system, and the car has a rear wheel torque bias, which gives a considerable power push from the rear wheels. Whenever the rear clutch pack is engaged, the rear wheels receive more torque and try to rotate faster than the front wheels.

2017 Ford Focus RS This little hot rod from Ford has a 350 hp 2.3 liter turbocharged four-cylinder with 350 lb-ft of torque. Since the Focus is basically a FWD vehicle and that amount of power would probably shred its front tires, Ford developed a

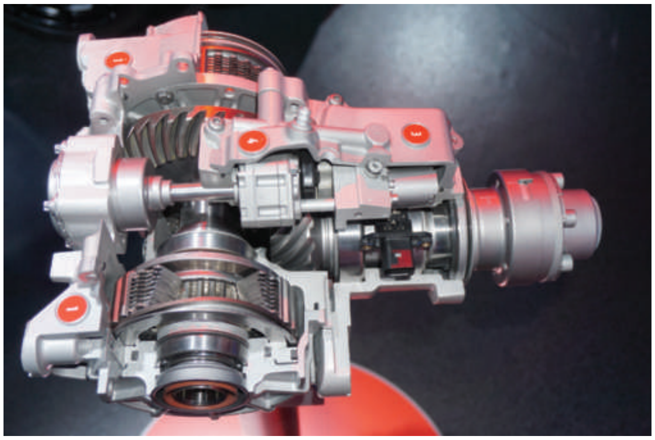

FIGURE 44-37 The Focus RS rear differential.

unique AWD system that can send up to 70 percent of the engine's torque to the rear wheels. This system utilizes a "Torque Vectoring Rear Drive Module" **(Figure 44–37)**, which consists of a differential and two clutches. These serve as rear axle couplings. The module can send all, some or none of the engine's torque to the left or right rear wheel. A computer calculates, based on a variety of inputs, how to limit wheel spin. It also helps the car by offering some differential action.

Active Twin Clutch AWD The GMC Arcadia with the All-Terrain package uses an active twin clutch AWD system. This system relies on a pair of electronically controlled clutches in place of the rear differential **(Figure 44–38)**. The system can partially or fully engage each rear wheel independently to maximize traction on slippery surfaces. It cannot overdrive the rear wheels, but it can deliver all of the rear axle's torque to the wheel with the traction.

Electronically Controlled Limited Slip Center Differential These units use electric and/or hydraulic actuators to engage a clutch that limits slip between the front and rear axles. They also have the ability to work independent of engine torque or friction at the wheels. Using inputs from a sensors and computer controls, these units offer a full range of operation from fully open to fully locked according to the needs. The systems can also be programed to predict when more slip is needed to prevent wheel slip before it occurs.

Torque Vectoring

Recently AWD vehicles have been equipped with electronically controlled torque vectoring systems. These are advanced traction and stability controls. They are capable of transferring torque, not only from front to rear, but also from side to side **(Figure 44–39)**. The benefits of these systems include improved overall handling, excellent cornering performance, and improved vehicle stability and safety.

A basic torque vectoring system can vary the torque between the front and rear wheels, in response to conditions. The system also monitors each wheel independently and will increase or decrease the amount of torque sent to each. To improve cornering, the system will automatically add torque to the outside rear wheel to allow the vehicle to turn quicker.

Through the vehicle's CAN system, the system monitors vehicle speed, individual wheel speeds, operating gear, braking force, steering angle, yaw rate, and other inputs.

Some AWD systems rely on a passive system in which the differential mechanically reacts to conditions to provide stability. Other current AWD systems

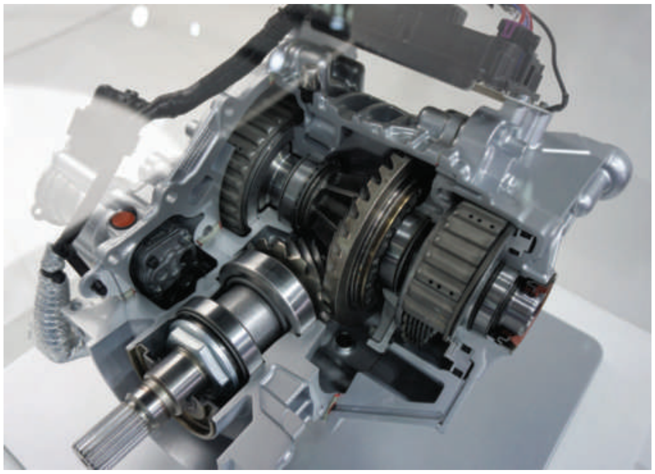

FIGURE 44-39 The Cadillac torque vectoring rear differential.

control wheel slip and stability by braking the wheel with little or no traction or by reducing the power from the engine. These are referred to as active brake systems. An AWD system with two open differentials, on very slippery surfaces, can get stuck as all the torque goes to the spinning tire. By applying the brake of the spinning tire, the system "locks" the differential, allowing torque to transfer to the opposite tire. True torque vectoring is achieved with special differentials that distribute power to the wheel or wheels that have traction; these are called active differential systems. Basic and true torque vectoring differentials can be found on some FWD vehicles.

GO TO Chapter 53 for more information on traction and stability control systems.

Active Differential Systems

Honda's Super Handling All-Wheel Drive (SH-AWD) is a full-time, fully automatic AWD traction and handling system with an active rear differential. The system does not have a center differential or a limited-slip differential at either axle.

The active differential is in the rear axle. It relies on planetary gears to increase the rotation speed, creating a speed difference between the input and output, and two electromagnetic clutches to transfer driving torque to the rear axles **(Figure 44–40)**. Each clutch is tied to an individual drive wheel and is electronically controlled. The system monitors many inputs that are available on the CAN bus to automatically add torque to the wheel with the most traction and the outside rear wheel during corners. Before the clutches are activated, wheel slip must be detected.

The system, which normally distributes torque 90 percent up front and 10 percent in the rear, can respond to conditions by allowing for a 50/50 split during acceleration or hard cornering. The system can then send some or all of that 50 percent going to the rear axle directly to the outside tire to make the vehicle bend into a corner more sharply.

Torque Vectoring Systems by ZF Late-model Audi Quattros and AWD BMWs are equipped with torque vectoring systems from ZF or Ricardo. Both of these systems are similar and rely on an active differential. These torque vectoring systems use wet clutches and planetary gearsets, in the front, center, and/or rear differentials **(Figure 44–41)**. They are controlled by electrical, electro-mechanical or electro-hydraulic systems.

One difference between the Audi system and BMW's is that Audi uses a wet clutch in the center differential that is mechanically controlled by the worm gears in its Torsen or crown gear differential. The rear differential has planetary gears connected to each drive axle that are controlled by motor-operated clutches to provide a difference in drive wheels'

rotational speed. Normally the front differential is open to allow for normal steering. The PCM controls the operation of the center and rear clutches of both systems. The system is tied to the stability control system, the active steering system, and the ABS. It helps steer the vehicle by sending torque to either of the rear wheels, which not only prevents wheel slip but also eliminates oversteer and understeer. When the possibility of understeer is detected, power to the front wheels is reduced. When oversteering is detected, more power is sent to the front wheels.

The systems are also designed to anticipate slippage by monitoring many inputs on the CAN bus and can provide yaw torque when the vehicle is cornering. The yaw torque forces the outside rear wheel to push forward while the inside rear wheel pulls back a bit. This is done by slightly altering the torque at the rear wheels. The overall effect is the same as the rear steering option offered on some vehicles.

Mitsubishi S-AWC Mitsubishi's Super All Wheel Control (S-AWC) is a full-time AWD system used in the Lancer Evolution. The system is integrated with the vehicle's active center differential (ACD), active yaw control (AYC), active stability control (ASC), and sports ABS components. This provides for regulation of torque and braking force at each wheel. The system is best described as an active differential (center and rear) with active braking at all wheels.

The ACD is an electronically controlled hydraulic multiplate clutch that limits the action of the center differential gears. The ACD regulates the torque split between the front and rear drive axles. The AYC acts like a limited slip differential by reducing rear-wheel slip to improve traction. It controls rear-wheel torque to limit the yaw of the vehicle to improve the vehicle's cornering performance. The ASC regulates engine power and the braking force at each wheel. This system improves vehicle stability and improves traction during acceleration. The system relies on two ECUs: one controls the ACD and AYC and the other controls ASC and ABS. The ECUs communicate to each other via the CAN bus.

Passive AWD Control Systems

Audi AWD vehicles carry the designation of "Quattro." Their basic system has evolved through the years. The early systems relied on Torsen-type differentials in the center and rear differentials. These systems are capable of varying the torque sent to any wheel of the vehicle. As time moved on, the basic system gained more electronic controls and is currently using a torque vectoring system by ZF.

Audi's Quattro permanent all-wheel drive system transfers torque from the front to the rear and side-to-side, as needed. The center differential compensates for the speed differences between the front and rear axles and distributes engine power between the front and rear wheels. The system automatically regulates the distribution of power within milliseconds. This action is based on engine speed and torque, wheel spreads, and longitudinal and lateral acceleration rates.

AWD Control Braking Systems

The Mercedes-Benz Torque Vectoring Brake system can apply braking to only the inside rear wheel during cornering. If the system detects understeer, it generates a quick burst of yaw torque. This allows the driver to have more control of the steering and the car can go through the corner with improved control.

This active brake torque vectoring system is integrated with Mercedes' stability control system and is always engaged. At the slightest hint of wheel slip, the system begins to brake that wheel or starts to decrease power to it.

Porsche Torque Vectoring (PTV) Although there are many AWD variations available, the 911 is unique in that it is rear-wheel drive with the engine mounted to the rear as well. A special assembly is used to transfer power from the rear to the front axle **(Figure 44–42)**. Torque vectoring is not currently available for the front and rear wheels.

The PTV system is a rear-wheel only active braking system first used in the 2010 Porsche 911 Turbo. The PTV can apply the brakes individually to stabilize and improve traction while the car is making a turn. The system relies on CAN inputs, such as steering

FIGURE 44–42 This Mitsubishi EVO is equipped with the S-AWC torque vectoring system.

angle, vehicle speed, throttle position, and yaw rate. PTV applies the brake on the inside rear wheel to minimize understeer while entering corners.

FWD Torque Vectoring

Ford introduced torque vectoring in its 2012 FWD Focus. Basically this torque vectoring system works like an electronic limited slip differential. The system relies on inputs from various sensors to apply an appropriate amount of brake force to the wheel with the least amount of traction.

Diagnosing 4WD and AWD Systems

Current 4WD and AWD systems are controlled by the PCM or a separate control module. Like all computer-monitored and computer-controlled systems, faults have to be identified by DTCs **(Figure 44–43).**

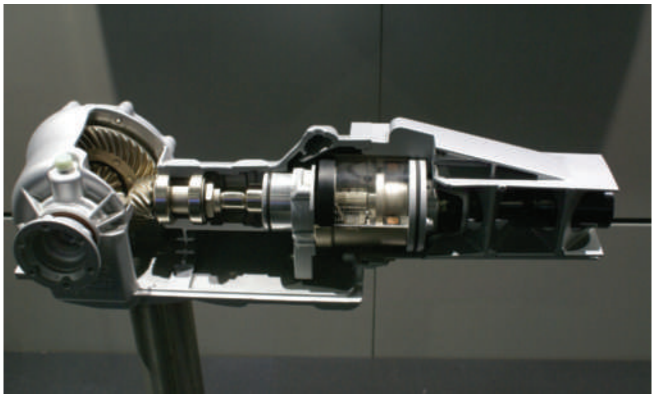

FIGURE 44–43 The assembly used to transfer engine power from the rear to the front axle in a Porsche 911.

STEP 3 If the cause was not visually evident, connect the scan tool to the DLC.

STEP 4 Note the DTCs retrieved.

STEP 5 Clear the DTCs.

STEP 6 Conduct the self-test for the 4WD control module.

STEP 7 If the DTCs retrieved are related to the concern, interpret the codes and follow the specific pinpoint tests for those codes **(Figure 44–44)**.

STEP 8 If the DTCs are not related to the concern or there are no DTCs, go to the manufacturer's symptom chart **(Figure 44–45)**.

STEP 9 Identify and repair the cause of the problem.

STEP 10 Verify the repair.

Basic System Diagnosis

Computer-controlled 4WD systems are diagnosed just like other computer-controlled systems. Make sure the scan tool can communicate with the vehicle by completing the test provided by the scan tool. If

the system has a separate self-diagnostic routine for the 4WD system, run that and then retrieve and record all DTCs. Always follow the procedures outlined by the manufacturer when connecting a scan tool to the system. Also always use the manufacturer's information when interpreting data.

Component Testing Individual inputs should be tested according to the procedures recommended by the manufacturer. The speed sensors are typically Hall-effect or magnetic pulse units. These are best checked with a scan tool or lab scope. Often, the manufacturer will recommend testing the sensors with a voltmeter or ohmmeter. Normally, these tests involve taking readings across a multiple-pin connector and at specific terminals.

The selector switch can be checked by connecting an ohmmeter across the terminals of the switch. As the switch is moved to various positions, the circuit through the switch should be either open or closed depending on the position. By referring to the wiring diagram, you can easily identify what should happen in the different switch positions. If the switch does not function as it should, it must be replaced.

When the transfer case shift motor is suspected as being faulty, begin diagnosis with a careful inspection. Then follow the manufacturer's procedures for testing it. Often, testing involves checking the motor for opens, shorts, and high resistance. If the motor is found to be defective, it must be replaced. Where placing the motor, make sure it is mounted correctly and its retaining bolts are tightened to specifications.

If the system uses a magnetic clutch, it can be checked with an ohmmeter. Noise from the clutch can be caused by a faulty clutch or a clutch that needs adjustment.

Shift-on-the-Fly Systems Shift-on-the-fly systems switch between 2WD and AWD electrically by a switch on the instrument panel. Many of these systems use electrically controlled vacuum motors to connect and disconnect the wheels from the axle or an electrical motor or electromagnetic clutch at the transfer case to transfer power to the additional axle. The 4WD indicator light will illuminate when 4WD is engaged. If there is a problem with the system or if 4WD cannot be engaged, the indicator lamp will blink to notify the driver of a problem. Diagnosis begins with watching the frequency of the blinking lamp. Check the service information for an interpretation of the blinking lamp.

If the vehicle will not engage in 4WD, there may be a faulty transfer case actuator motor or faulty vacuum solenoid assembly. If the motor in the transfer case is a possible cause, remove it and check its operation **(Figure 44–46)**. Check the transfer case and repair or replace any faulty components if the motor is not the cause of the problem. If no problem is found in the transfer case, it is likely that the electronic control unit is faulty.

Check for engine vacuum at the actuator and/or solenoid before checking anything else if the vacuum actuator is suspect. If no vacuum is present when the engine is running, check the transfer position switch. A voltage signal should be sent to the

vacuum solenoid when 4WD is selected. If no signal is being sent, then the switch or switch circuit is faulty. However, if the solenoid is receiving a voltage signal, suspect a faulty solenoid assembly.

Check the vacuum circuit for leaks if there are no electrical problems. Vacuum solenoids can be checked by connecting jumper leads from the battery to the terminals of the solenoid. Remove the vacuum solenoids and connect the battery to the terminals of each solenoid. Connect a hand-held vacuum pump to the inlet port of the solenoid and a vacuum gauge to the port for axle engagement. With the battery connected to the solenoid, there should be vacuum at the outlet port to the axle. Move the vacuum gauge to the other outlet port. Vacuum should not be present there. Now disconnect the battery from the solenoid. Recheck the vacuum at the outlet ports. A good solenoid will have vacuum only at the disengagement port when vacuum is applied and the solenoid is not connected to the battery.

On-Demand Systems On-demand systems operate at the discretion of the PCM or override controls selected by the driver. The division of power between the front and rear axles is controlled by the output clutch at the transfer case. The activity of the clutch is controlled by regulating its duty cycle. During normal operation, the duty cycle is low. This allows for a slight speed difference between the front and rear drive shafts, which normally occurs when the vehicle is moving through a curve. When slip is detected at the rear wheels, the duty cycle to the clutch is increased until the difference between the front and rear drive axles is reduced.

To vary the torque split, a computer monitors many things, especially the rotational speeds of the front and rear drive axles. Some systems rely on wheel-speed sensors for this, whereas others have additional speed sensors on the front and rear output shafts from the transfer case. Many of the inputs to the electronic module for 4WD are shared and work with other systems, and they are available on CAN **(Figure 44–47)**. The best place to start when diagnosing these systems is the service information. Go to the section on the system and identify the components involved in the various modes of operation.

AWD Systems Most AWD systems have a viscous coupling. A viscous coupling can be checked with a torque bias test. This check measures the torque required to rotate one front wheel when it is raised off the ground while the others are on the ground. The transfer case should be in 4WD and the transmission in neutral; compare the measured torque to specifications. A worn coupling is indicated by low readings.

Problems with AWD systems normally occur with the controls that provide for braking efficiency and AWD in reverse gear. Some systems use a vacuum solenoid setup to provide AWD in reverse. The

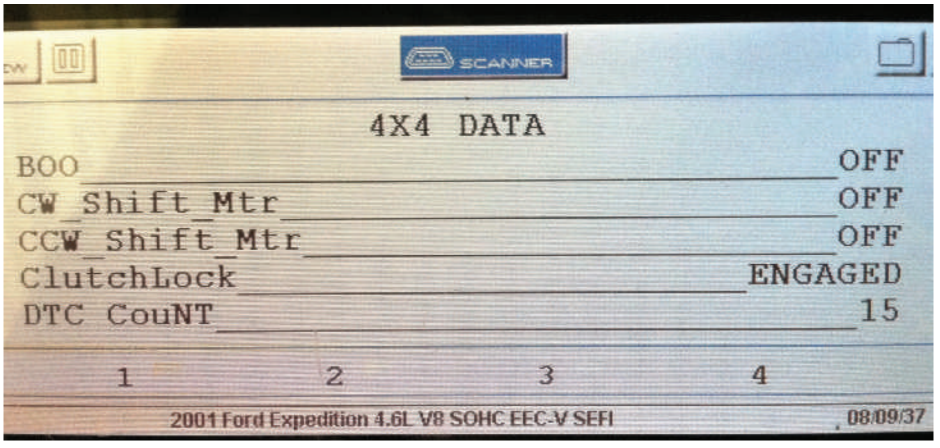

FIGURE 44–47 Scan data for a 4WD system.

solenoids are used to bypass the overrunning clutch. If AWD is not available in reverse gear, suspect the vacuum solenoids, their controls, or the dog-clutch assembly.

An overrunning clutch is used to prevent any feedback of front-wheel braking torque to the rear wheels. This allows the brake system to control braking as if it were a 2WD vehicle. The controls for this feature vary with the manufacturer, and you should always follow the troubleshooting charts provided by the manufacturer.

Axle Hub Diagnosis

Front hubs may make a ratcheting sound when water or dirt has entered the hub and contaminated the lubricant. This prevents free movement of the components in the hub. A ratcheting sound from an automatic locking hub may indicate that the hub on the opposite side of the axle is not disengaging.

Locking hubs can be quickly checked by rotating the brake drum or rotor slightly and turning the hub selector into the lock position. A click should be heard when the hub engages the axle, and the axle should now turn with the hub. Next, with the hub still turning, turn the selector to the free position. The axle should now be free of the hub. If both of these events do not happen, the hub assembly needs to be repaired or replaced.

Hubs can also be checked by raising the front wheels and spinning the front tires. Next, engage 4WD and spin the tire. If the hub is locked, both the tire and the axle will spin. Release 4WD and spin the tire again to make sure the hub releases. If the hub does not lock or stays locked, the hub needs to be serviced or replaced.

Wheel Bearings

To check the adjustment of the wheel bearings, raise the front of the vehicle. Grasp each front tire at the front and rear and push the wheel inward and outward. If any free play is noticed between the hub, rotor, and front spindle, adjust the wheel bearings.

Older vehicles with serviceable wheel bearings should be disassembled and serviced as part of normal maintenance **(Figure 44–48)** or any time the hubs have been submerged in water. During normal operation the bearings get warm and when they are quickly cooled off by the splash of water, their lubricant breaks down and the bearings can be destroyed. Always replace the bearings if they are worn or damaged.

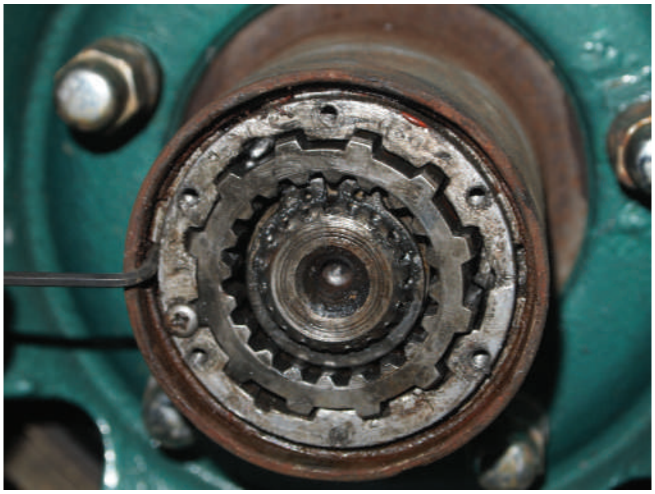

FIGURE 44–48 A manual locking hub wheel bearing retainer.

Another frequent cause of wheel bearing failure is the use of oversized tires mounted on wheels with substantial offset. These switch the load from the large inner bearing to the small outer wheel bearing, which was never intended to do much more than stabilize the wheel.

Servicing 4WD Vehicles

The components of 4WD vehicles are serviced in basically the same way as the same parts of a 2WD vehicle. Also it is important that the U-joints, slip joints, or CV joints in the drivetrain be lubed on a regular basis. To service the drive shafts and U-joints on a 4WD vehicle, use the general instructions given for a cross U-joint. A four-wheel-drive simply uses two drive shafts instead of one.

Maintenance

It is also important to make sure the transfer case and differentials have the correct fluid and are filled to the correct level. To check the differential fluid, locate the plug. Most manufacturers require the use of either a $^3/_8$ inch drive ratchet or a wrench to remove the plug **(Figure 44–49)**. Be careful not to damage it or its threads. The fluid level should be up to the bottom of the fill plug hole. If fluid is needed, refer to the owner's manual or service information for the correct lubricant.

Some AWD vehicles, like the Pilot and CR-V from Honda, require special lubricants for the viscous clutches and require the fluid to be replaced per the maintenance schedule. Failure to maintain the fluid can result in noise and damage to the clutch. Make

FIGURE 44-49 The fluid plugs on a transfer case.

sure your customers who own these types of vehicles are familiar with the special maintenance needs so services can be performed before a problem arises.

Most transfer cases and PTUs have a plug in the side of the case for checking the oil level. The oil should be at the bottom of this opening. Some transfer cases use ATF and others use gear oil; always use the recommended oil.

4WD and AWD Tires

Because 4WD and AWD vehicles can direct torque to the front and rear and side-to-side tires, maintaining proper rolling circumference of the tires is critical. Most manufacturers recommend tire circumference be maintained within ¼ to ½ inch of each other. If the difference in tire circumference is excessive, the speed differences may result in the 4WD or AWD system attempting to manage torque and traction all the time. This could result in rapid wear and damage to viscous clutches and other components.

In the event the owner of a 4WD or AWD vehicle has a tire blow out, replacing all four tires may be the only way to maintain the correct tire circumferences. Replacing one tire while leaving the remaining three worn may cause enough of variation in rotational speeds to affect the 4WD or AWD system. And, depending on the system, even replacing both tires on one axle while leaving the other two old tires installed on the other axle may cause problems.

GO TO Chapter 40 for a detailed look at servicing joints and drive shafts.

Servicing the Transfer Case

Be sure to check the manufacturer's service information for specific transfer case repair and overhaul procedures. It gives details for the particular make and model of transfer case to be worked on.

To remove the transfer case, raise and support the vehicle. Remove any skid plates and brace rods that block access to the transfer case or that are attached to it. Disconnect and remove all drive shaft assemblies. Be sure to mark the parts and their relative positions on their yokes so that the proper driveline balance can be maintained when reassembled. Disconnect the linkage to the transfer case shift lever. Also, disconnect all wires connected to the transfer case. Support the transfer case using a transmission jack and remove the fasteners that secure it to the transmission. Slide the transfer case off the rear of the transmission and remove it from the vehicle.

Once the transfer case has been removed from the vehicle and safely supported, inspect it for signs of oil leaks. Remove the case cover and then carefully loosen and drive out the pins that hold the shift forks in place. Remove the front output shafts and chain drive or gearsets from the case. Keep in mind that some cases use chain drives, whereas others use spur or helical cut gearsets to transfer torque from the transaxle or transmission to the output shafts. Planetary gearsets provide the necessary gear reductions in some transfer cases. Photo Sequence 39 shows the procedure for disassembling a Warner 13-56 transfer case, which is a commonly used unit.

Clean and carefully inspect all parts for damage and wear. Check the slack in the chain drive according to the procedure given in the service manual. Replace any defective parts. It may be necessary to measure the shaft assembly end play. If excessive, new snaprings and shims may be used to correct the situation.

When reassembling the transfer case, the procedure is essentially the reverse of the removal. Be sure to use new gaskets between the covers when reassembling the unit. Photo Sequence 40 shows the procedure for reassembling a Warner 13-56 transfer case.

Caution! When removing and working on a transfer case, be sure to support it on a transmission jack or safety stands. The unit is heavy and, if dropped, could cause part damage and personal injury.

Front Axles and Hubs

The axles and locking hubs must be removed before the front differential and final drive assembly can be removed from the axle housing. Removing these components requires special procedures, and each type of 4WD system requires its own specific procedure.

GO TO Chapter 40 for details on serving a final drive unit in a transaxle.

Removal of the axle shafts begins with the removal of the hubs. Normally, the procedures for replacing manual hubs are somewhat different from those for replacing automatic hubs. Locking hubs are not serviceable; therefore, service of the hubs consists of merely replacing them. Also, the procedure for the replacement of the hubs varies with the type of hub and the manufacturer. The following are general procedures for the removal and installation of both manual and automatic locking hubs. Always follow the specific procedures for the type of hub you are servicing.

Manual Locking Hub To remove a manual hub, set the hub's control knob to the "Free" or unlocked position. Then remove the cover bolts and the outer snapring. If hubs are equipped with shims, remove them as well. Then remove the drive flange or gear from the axle. Now remove the bolts that attach the hub body to the hub. The hub assembly can now be pulled from the axle shaft. After the hub assembly has been removed, inspect the splines of the axle shaft for nicks and burrs.

To install a manual hub, separate the base and handle units of the hub lock assembly. Apply a light coat of grease to the axle shaft splines and the hub lock base. Also apply a light coating of lubricant to the O-ring. Make sure the gasket surface is smooth and clean, then place a new hub gasket onto the hub. Set the control handle to the unlocked position and install the hub assembly and the snapring onto the axle shaft. Tighten the attaching bolts to the specified torque. Install the hub cover with a new gasket onto the hub and tighten the remaining attaching bolts to specifications. Check the control handle for ease of operation.

Automatic Locking Hub There are basically two designs of automatic locking hubs: internally and externally retained. The procedure for servicing automatic hubs depends on how they are retained. Remove the bolts from the outer cap assembly and pull the cap off the body of the hub. Then remove the axle shaft bolt, lock washer, and axle shaft stop. In the wheel hub there is a groove that retains a lock ring; remove it and slide the hub assembly off the wheel's hub. Then loosen the set screws in the spindle locknut until their heads are flush with the face of the locknut. Remove the spindle locknut.

To install an automatic hub, adjust the wheel bearings and install the spindle locknut and tighten it to specifications. Firmly tighten the locking set screws. Apply multipurpose grease to the inner splines of the hub; do not pack the hub with grease. Slide the assembly into the wheel hub. Push firmly on the body until it seats in the hub. Then install the lock ring in the groove of the wheel hub. Place the lock washer and axle shaft stop onto the axle bolt. Install the bolt and tighten it to specifications. Apply a small amount of lube to the seal on the cap assembly. Do not grease the cap assembly. Install the cap assembly over the body assembly and into the wheel hub. Install the attaching bolts and tighten them to specifications. Firmly turn the control from stop to stop to check the assembly. Then set both hub controls in the same position: "auto" or "lock."

Wheel Bearings

The front-wheel bearings on a 4WD vehicle should be disassembled, cleaned, inspected, and lubricated on a regular basis. Upon reassembly, it is very important that the bearings be properly adjusted. The procedure for doing this is similar to other wheel bearings. However, because of the load on the bearings, the adjustment is more critical.

To adjust the wheel bearings, begin by removing the snapring at the end of the spindle, the axle shaft spacer, needle thrust washer, bearing spacer, outer wheel bearing locknut, and bearing washer. Then loosen the inner bearing locknut and tighten it fully to seat the bearings. The wheel bearing locknuts on most 4WD vehicles require the use of a four- or six-pronged spanner wrench. Spin the brake rotor on the spindle, then loosen the inner bearing locknut approximately ¼ turn. Install the outer bearing locknut and tighten it to the specified amount, usually 70 to 90 ft.-lb (95 to 122 Nm). Assemble the remaining parts of the hub assembly, making sure that the snapring is fully seated in its groove on the axle.

SUMMARY

- The importance of excellent traction and the benefits of four-wheel and all-wheel drive systems become readily apparent in snow or heavy rain.
- The heart of most conventional 4WD systems is the transfer case.
- The interaxle is placed in the transfer case to operate in the same fashion as the differentials at the axles. The only difference is that the transfer differential controls the speed of the drivelines instead of the axles.
- Many vehicles require that the front hubs be in a locked condition to operate as 4WD vehicles. This lockup may be made either manually or automatically.
- On 4WD vehicles with on-the-fly shifting, it is not necessary to come to a complete stop when changing operational modes.
- Components of 4WD vehicles can be serviced in basically the same manner as the identical components on a 2WD vehicle.
- All-wheel drive vehicles may use a viscous clutch, rather than a transfer case, to drive the axle with low tractive effort.
- Many AWD vehicles have a third differential, called an interaxle (center) differential, instead of a transfer case.

SUSPENSION AND STEERING SYSTEMS

SECTION 7

CHAPTER 45

TIRES AND WHEELS

OBJECTIVES

- Describe basic wheel and hub design.
- Explain the tire ratings and designations in use today.
- Describe why certain factors affect tire performance, including inflation pressure, tire rotation, and tread wear.
- Describe the operation, diagnosis, and service for a tire pressure monitor.
- Remove and install a wheel and tire assembly.
- Repair a damaged tire.
- Describe the differences between static balance and dynamic balance.

Tire and wheel assemblies provide the only connection between the road and the vehicle. Tire design has improved dramatically during the past few years. Modern tires require increased attention to achieve their full potential of extended service and correct ride control. Tire wear that is uneven or premature is usually a good indicator of steering and suspension system problems. Tires, therefore, become not only a good diagnostic aid to a technician, but can also be clear evidence to the customer that there is need for service.

Wheels

Wheels are made of either stamped or pressed steel discs riveted or welded together. They are also available in the form of aluminum or magnesium rims that are die-cast or forged **(Figure 45–1)**. Magnesium wheels are commonly referred to as mag wheels, although they are usually made of an aluminum alloy. Aluminum wheels are lighter in weight when compared with the stamped steel type. This weight savings is important because the wheels and tires on a vehicle are unsprung weight. A few vehicles offer carbon fiber wheels as options to further help save weight. Though expensive, carbon fiber wheels can save several pounds per wheel.

FIGURE 45-1 An alloy wheel on a late-model car.

SHOP TALK

Sprung weight represents the weight of the vehicle that is supported by the suspension. The suspension and wheels are unsprung weight. Lower amounts of unsprung weight make the vehicle handle better, primarily on irregular surfaces. It also gives a better ride. This is because when a tire hits a bump, the shock is moved through the tire and wheel to the suspension. The shock that is not absorbed by the suspension then moves to the rest of the vehicle. When the unsprung weight is high, that weight and the shock from the road must be absorbed by the suspension. This means more shock will be passed to the rest of the vehicle.

Near the center of the wheel are mounting holes that are tapered to fit tapered mounting nuts (lug nuts) that center the wheel over the hub. The rim has a hole for the tire's valve stem and a drop center area designed to allow for easy tire removal and installation. Wheel offset is the vertical distance between the centerline of the rim and the mounting face of the wheel. The offset is considered positive if the centerline of the rim is inboard of the mounting face and negative if outboard of the mounting face. The amount and type of offset is critical because changing the wheel offset changes the front suspension loading as well as the scrub radius.

GO TO Chapter 49 for details on scrub radius and wheel alignment.

The wheel is bolted to a **hub**, either by lug bolts that pass through the wheel and thread into the hub, or by studs that protrude from the hub. In the case of studs, special lug nuts are required. A few vehicles have left-hand threads (which turn counterclockwise to tighten) on the driver's side and right-hand threads (which turn clockwise to tighten) on the passenger's side. All other vehicles use right-hand threads on both sides. Aftermarket wheels may have additional lug holes so that the wheels can fit a variety of stud patterns. Installing aftermarket wheels may require the use of a centerbore spacer in the wheel. The spacer is used to match the centerbore of the wheel to fit the hub of the vehicle.

Wheel size is designated by rim width and rim diameter **(Figure 45–2A)**. Rim width is determined by measuring across the rim between the flanges. Rim diameter is measured across the bead seating areas from the top to the bottom of the wheel. Wheel bolt pattern is determined by the distance between the studs **(Figure 45–2B)**. Rims have safety ridges near their lips. In the event of a tire blowout, these ridges tend to keep the tire from moving into the dropped center and from coming off the wheel.

Replacement wheels must be equal to the original equipment wheels in load capacity, diameter, width, offset, and mounting configuration. An incorrect wheel can affect wheel and bearing life, ground and tire clearance, or speedometer and odometer calibrations. A wrong size wheel can also affect the antilock brake system. Using the wrong size tire or wheel or improperly inflated tires will affect the rotational speed of the tire, and the ABS will be unable to operate correctly. Aftermarket replacement wheels

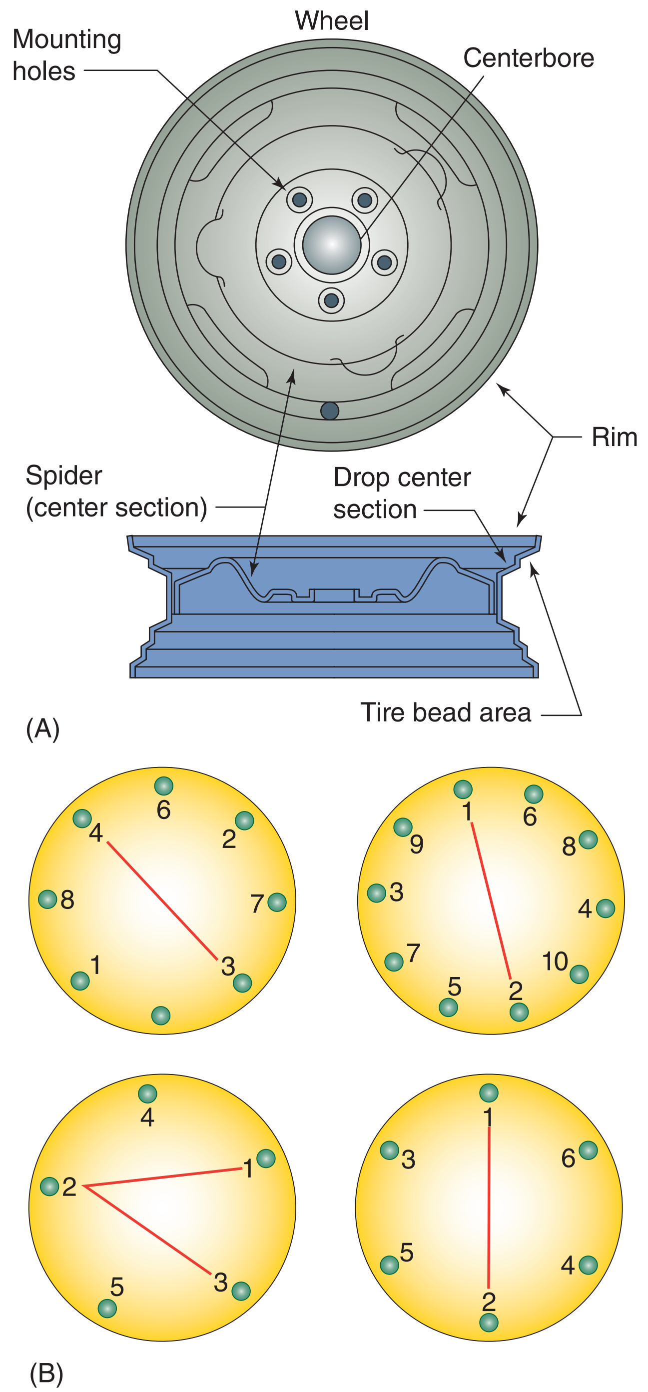

FIGURE 45-2 (A) Wheel dimensions are important when replacing tires. (B) Wheel bolt pattern is determined by the distance between the studs.

may not accommodate the factory tire pressure monitoring sensors as well. Due to the legal aspects regarding TPMS, make sure any replacement wheels are able to be fitted with pressure sensors if the vehicle is equipped with TPMS.

Some performance-oriented cars are equipped with different-sized wheels at the front and rear. It is important that the specific size wheel be at the specific axle. The wider or larger wheels are designed to use different-sized tires. For example, a Porsche 911 has 8.5 × 19 front wheels that are fitted with 235/40 ZR 19 tires. The rear is equipped with 11.5 × 19 wheels that carry 295/35 ZR 19 tires.

Tires

The primary purpose of tires is to provide traction. Tires also help the suspension absorb road shocks, but this is a side benefit. They must perform under a variety of conditions. The road might be wet or dry or paved with asphalt, concrete, or gravel, or there might be no road at all. The car might be traveling slowly on a straight road, or moving quickly through curves or over hills. All of these conditions call for special requirements that must be present, at least to some degree, in all tires.

In addition to providing good traction, tires are also designed to carry the weight of the vehicle, to withstand side thrust over varying speeds and conditions, and to transfer braking and driving torque to the road. All of this has to occur on a contact patch that may be as small as 35 square inches (226 square cm) per tire. As a tire rolls on the road, friction is created between the tire and the road. This friction gives the tire its traction. Although good traction is desirable, it must be limited. Too much traction means there is much friction. Too much friction means there is a lot of rolling resistance. Rolling resistance wastes engine power and fuel; therefore, it must be kept to a minimal level. This dilemma is a major concern in the design of today's tires.

Tire Construction

Early vehicle tires were solid rubber. These were replaced with pneumatic tires, which are filled with air. Tires with tubes, similar to bicycle tires, were used for many years but were replaced by tubeless designs in the 1950s.

A tubeless tire has a soft inner lining that keeps air from leaking between the tire and rim. On some tires, this inner lining can form a seal around a nail or other object that punctures the tread. A self-sealing tire holds in air even after the object is removed. The key to this sealing is a lining of sticky rubber compound on the inside of the tread area that will seal a hole up to 3⁄16 inch (4.76 mm).

A tire air valve has a central core that is spring-loaded to allow air to pass inward only, unless the pin is depressed. If the core becomes defective, it can be unscrewed and replaced. The airtight cap on

the end of the valve provides extra protection against valve leakage. A tubeless tire is mounted on a special rim that retains air between the rim and the tire casing when the tire is inflated.

Figure 45–3 shows a cutaway view of a typical tire. The cord body or casing consists of layers of rubber-impregnated cords, called **plies**, that are bonded into a solid unit. Typically, passenger car and light truck tires are made of 4 plies. Bias tires were actually constructed of many plies, up to 10 or 12 layers to increase tire strength. Modern tires do not require the many layers to increase the tire's load carrying capacity. The **bead** is the portion of the tire that helps keep it in contact with the rim of the wheel. It also provides the air seal on tubeless tires. The bead is constructed of a heavy band of steel wire wrapped into the inner circumference of the tire's ply structure. The **tread**, or crown, is the portion of the tire that comes in contact with the road surface. It is a pattern of grooves and ribs that provides traction. The grooves are designed to drain off water, while the ribs grip the road surface. Tread thickness varies with tire quality. On some tires, small cuts, called sipes, are molded into the ribs of the tread. These sipes open as the tire flexes on the road, offering additional gripping action, especially on wet road surfaces. The sidewalls are the sides of the tire's body. They are constructed of thinner material than the tread to offer greater flexibility.

FIGURE 45–3 A typical tubeless tire.

The tire body and belt material can be made of rayon, nylon, polyester, fiberglass, steel, amarid, or kevlar. Each has its advantages and disadvantages. For instance, rayon and cord tires are low in cost and give a good ride, but do not have the inherent strength needed to cope with long high-speed runs or extended periods of abusive use on rough roads. Nylon-cord tires generally give a slightly harder ride than rayon—especially for the first few miles after the car has been parked—but offer greater toughness and resistance to road damage. Polyester and fiberglass tires offer many of the best qualities of rayon and nylon, but without the disadvantages. They run as smoothly as rayon tires but are much tougher. They are almost as tough as nylon, but give a much smoother ride. Steel is tougher than fiberglass or polyester, but it gives a slightly rougher ride because the steel cord does not give under impact, as do fabric plies. Amarid and kevlar cords are lighter than steel cords and, pound for pound, stronger than steel.

There are three basic types of tire construction: bias ply, belted bias, and radial ply **(Figure 45–4)**. Bias ply

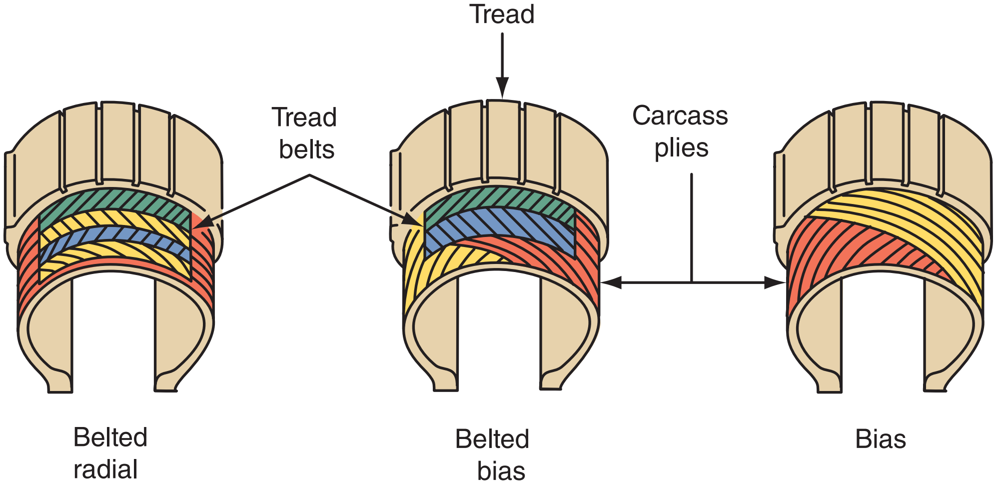

FIGURE 45–4 The construction of the three basic types of tires.

and belted bias tires are only used on off-road heavy equipment, some trailers, and older cars. Today, nearly all road-going vehicles are fitted with radial tires.

Bias ply tires have fabric plies that run alternatively and form a crisscross design. The angle varies from 30 to 38 degrees with the centerline of the tire. Belted bias ply tires are similar to bias ply tires, except that two or more belts run the circumference of the tire under the tread. This construction gives strength to the sidewall and greater stability to the tread.

Radial ply tires have body cords that extend from bead to bead at an angle of about 90 degrees or "radial" to the circumferential centerline of the tire—plus two or more layers of relatively inflexible belts under the tread. The construction of various combinations of rayon, nylon, fiberglass, and steel gives greater strength to the tread area and flexibility to the sidewall. The belts restrict tread motion during contact with the road, thus improving tread life and traction. Radial ply tires also offer greater fuel economy, increased skid resistance, and more positive braking.

Specialty Tires

Specialty tires reflect the advances made in tire development. These tires are designed for specific road conditions or applications. All-season tires are designed to perform well on all types of road conditions, but they are not excellent performers on all road surfaces. To provide traction in the snow and mud, at least 25 percent of the tread area is void **(Figure 45–5)**. This leaves open areas for the snow or mud to move into as the tire rotates. The open spaces also give the tires some bite as they move. The remaining tread area is designed to provide good traction on normal surfaces.

FIGURE 45–5 A directional all-season radial tire.

> **SHOP TALK**
>
> **Snow tires are designed to increase traction in the snow. They should be installed on all wheels and replaced with normal tires once the season changes.**

Tires can also be designed for heavy snow. These are commonly called "snow tires." The tread area is much more aggressive, with larger voids than all-season tires. Because of the decreased contact with the road, these tires do not provide good traction during normal conditions.

Studded tires provide superior traction on ice but are slowly disappearing from the tire market because their performance on dry surfaces is poor. In addition, many states have outlawed their use because they damage the road and can be a safety hazard on dry surfaces. Because the studs have more contact on the road than the tire's rubber, it is easy for the tire to slide on the road during cornering and stopping. The studs offer much less friction than the rubber tire tread.

Tires can be designed to be great on dry surfaces or wet surfaces. These are often called "All-Season" tires and offer fair traction on snow and ice. However, it is nearly impossible to have a tire that performs extremely well on all surfaces. Tires designed for dry and smooth roads do not need a tread pattern. They can be "slicks." The smooth surface gives the tires maximum grip on a smooth, dry surface. However, when a slick hits a wet spot, there is no traction. The tire simply slides on the water.

Tires designed for wet surfaces have tread designs that move the road's water behind and to the side of the tire. Moving the water is the only way a tire can grip the road. When too much water separates the tire from the road, hydroplaning takes place. This causes the tire to lift off the road and rotate on a layer of water. Traction is reduced and this can create an unsafe condition. Needless to say, when a tire has many directed and open channels for water in its tread, less rubber meets the road.

Some cars are equipped with summer performance tires. This type of tire maximizes handling and road holding but only in warm weather. In most cases, these tires should not be used in snow or when temperatures are 40 °F (4.4 °C) or below. Use of the tires below the recommended temperatures

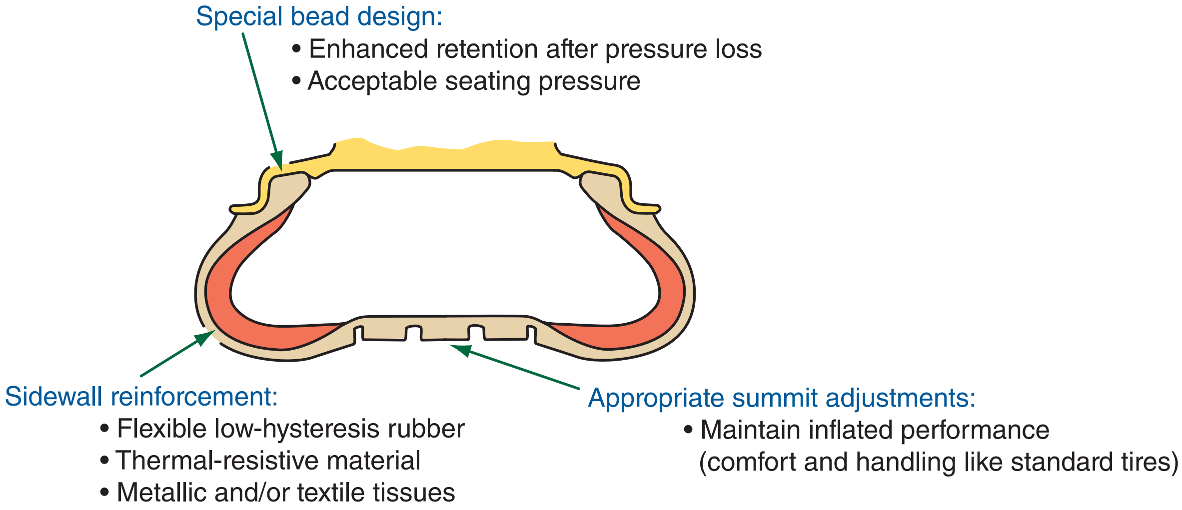

FIGURE 45-6 Features of a run-flat tire.

can cause reduced traction as the tires may not develop enough heat to become "sticky."

Run-Flat and Self-Sealing Tires

There are several types of run-flat tires available. Vehicles equipped with these have no spare tire or jack in the luggage compartment. Run-flats can be divided into two categories: self-supporting and auxiliary supported systems. Each of these uses different ways to allow a vehicle to be driven after a tire is punctured.

Self-Supporting When a self-supporting tire loses all of its air pressure, it is able to temporarily carry the weight of the vehicle and allow the vehicle to be driven. This is a result of the tire's construction. These tires have reinforced sidewalls and special beads **(Figure 45–6)**. The first "run-flat" tire available on a regular production vehicle was a self-supporting tire that was offered as an option on the 1994 Chevrolet Corvette. Today, many tire manufacturers offer self-supporting tires and self-supporting tires are standard equipment on most BMW models. Typically, a self-supporting tire can be driven for 50 miles (80 km) at speeds up to 55 mph (89 km/h) after it has lost air pressure.

Auxiliary Supported Run-Flat Systems Auxiliary supported systems are much different from other run-flat tires. They are systems that have special tires and wheels. The basis of these systems is a solid supporting ring that allows a flat tire's tread to rest on a support ring attached to the wheel when the tire loses pressure **(Figure 45–7)**. This support ring allows the tire to behave as it would when it was inflated. The wheel and tire are designed to prevent the tire from coming loose from the wheel when air pressure is lost. The most common system is Michelin's PAX system, which was introduced in 1996. This system allows the driver to drive the vehicle up to 125 miles (201 km) at 55 mph (89 km/h) before it needs service. This type of tire requires a special wheel and neither the wheel nor tire are interchangeable with standard wheels and tires.

FIGURE 45-7 A cutaway of a run-flat tire with an insert for support in case the tire goes very flat.

Self-Sealing Self-sealing tires are designed to quickly and permanently seal most tread-area punctures. The tires are constructed like other tires, but there is an additional lining inside the tire under the tread area. The lining is coated with a sealant that can permanently seal most punctures up to $^3/_{16}$ inch (4.76 mm) in diameter. The lining seals the area around the puncture and can fill in the hole once the object is removed from the tire **(Figure 45–8)**. There is no provision for reinflating the tire, so the tire will need to be inflated after the repair.

Tread Designs

The real purpose of a tire is to get a grip on the road. The ideal tire is one that wears little, holds the road well to provide sure handling and braking, and provides a cushion from road shock. The ideal tire should also provide maximum grip on dry roads, wet roads, and snow and ice, and operate quietly at any speed. This is a tall order, so tire manufacturers compromise on one or two of these qualities for the sake of excelling at another. A tire's tread design dictates what the tire will excel at.

There are basically four categories of tread patterns: directional, nondirectional, symmetric, and asymmetric.

A directional tire is mounted so that it revolves in a particular direction. These tires have an arrow on the sidewalls that show the designed direction of travel. A directional tire offers good performance only when it is rotating in the direction in which it was designed to rotate **(Figure 45–9A)**. Directional tread patterns are used with all-season tires to more effectively channel water from under the tire and improve wet traction. Many sports car tires also use a directional tread design. A nondirectional tire has the same handling qualities in either direction of rotation.

FIGURE 45-8 The action of a self-sealing tire.

The most common and basic tread designs are nondirectional. A symmetric tire has the same tread pattern on both sides of the tire. An asymmetrical tire has a tread design that is different from one side to the other **(Figure 45–9B)**. Asymmetrical tires are typically designed to provide good grip when traveling straight (the inside half) and good grip in turns (the outside half of the tread). Some asymmetric tires are also directional tires.

The number and size of the blocks, sipes, and grooves on a tire's tread not only determine how much rubber contacts the road and how much water can be displaced, they also determine how quiet the tire will be during travel. The more aggressive the tread, the more noise it will make. This statement is especially true if the tire's tread is made

(A)

(B)

FIGURE 45-9 There are many different tread designs available for today's vehicles. (A) This is a directional tread design. (B) This is an asymmetrical tread design.

SHOP TALK

Whenever a customer wants a better handling tire, make sure that he or she knows that a better gripping tire may make more noise and not wear as long as other tires. Knowing what design of tire will meet a customer's needs is a science. Always consult with a tire specialist before recommending one tire or another.

of a hard compound. Softer tires typically make less noise but wear more quickly. Soft tires also adhere to the road better.

Channels are cut into a tire's tread to allow water to move away from the tire's direction of travel. The deeper the channel, the more water the tire can move. The disadvantage of these channels is decreased road contact.

LRR Tires Some late-model vehicles are equipped with low rolling resistance (LRR) tires. These are designed to increase fuel economy and are found on some hybrid and electric vehicles. Rolling resistance is basically the power consumed by the tire's contact with the road and the flexing of its sidewalls. It is estimated that 5 to 15 percent of a vehicle's fuel consumption is used to overcome a tire's rolling resistance. Therefore, reduce the rolling resistance and use less fuel. The use of LRRs comes with a cost; they typically have less surface contact on the road and are not the best handling tires.

Spare Tires

Nearly all vehicles are equipped with a spare tire to be used in case one of the vehicle's tires loses air and goes flat. A spare tire can be a tire that matches the tires on the vehicle, usually called a full-size spare, or can be a compact spare. Compact spares are designed to reduce weight and storage space but still provide the driver with a tire in the case of an emergency. Compact tires are typically one of three types: high-pressure mini spare, space-saver spare, and lightweight skin spare.

A high-pressure mini-spare tire is a temporary tire **(Figure 45–10)**. It should not be used for extended mileage or for speeds above 50 mph (80 km/h). These tires typically require an inflation pressure of 60 psi (415 kPa). A space-saver spare must be blown up with a compressor that operates from the cigarette

CUSTOMER CARE

Make sure you warn your customer that a mini, space-saver, or similar type compact spare should be used only as a temporary tire. It should never be used as a regular tire. Any continuous use of a temporary spare will result in tire failure, which can cause loss of control and injury to the vehicle's occupants. It can also cause differential gear wear and will affect ABS and traction control operation.

lighter or a built-in air compressor. A skin spare is a normal bias ply type tire with a reduced tread depth.

Some cars do not have spare tires, even if they are not fitted with run-flat tires. Instead, these cars have a high-pressure air pump and a can of tire sealant in the trunk. Normally the sealant will allow the car to be driven until the tire can be properly repaired.

Tire Ratings and Designations

The construction of a tire depends on its application. Needless to say, there are many different tires. These differences are based on not only size, but their construction to meet intended driving conditions. There are also standards that tire manufacturers must meet to ensure that the tire will be safe, not wear too rapidly, and offer good road isolation for the passengers

in the vehicle. The uniqueness of each tire is represented by information given on the sidewall of every tire produced. In fact, everything you need to know about a tire is imprinted on the tire **(Figure 45–11)**.

Tire Size

The best way to describe and explain the information given on the sidewall of a tire is to look at an example. Look at the tire size designation of P215/65 R15 89H and see what it tells.

On a **P**215/65 R15 89H tire, the *P* represents the application of the tire; in this case P = passenger car. If the tire had an "LT" designation, the tire would be for a light truck.

The *215* in P**215**/65 R15 89H represents the width of the tire measured in millimeters from sidewall to sidewall. This tire width is 215 millimeters. This is also called section width, and it varies with the wheel (rim) on which the tire is mounted. A wide rim increases the section width, whereas a narrow one decreases it. The measurement given on the tire was taken with the tire on a specific rim.

The *65* in P215/**65** R15 89H indicates the **aspect ratio** or profile (series) of the tire **(Figure 45–12)**. A tire's aspect ratio is the relationship of its cross-sectional

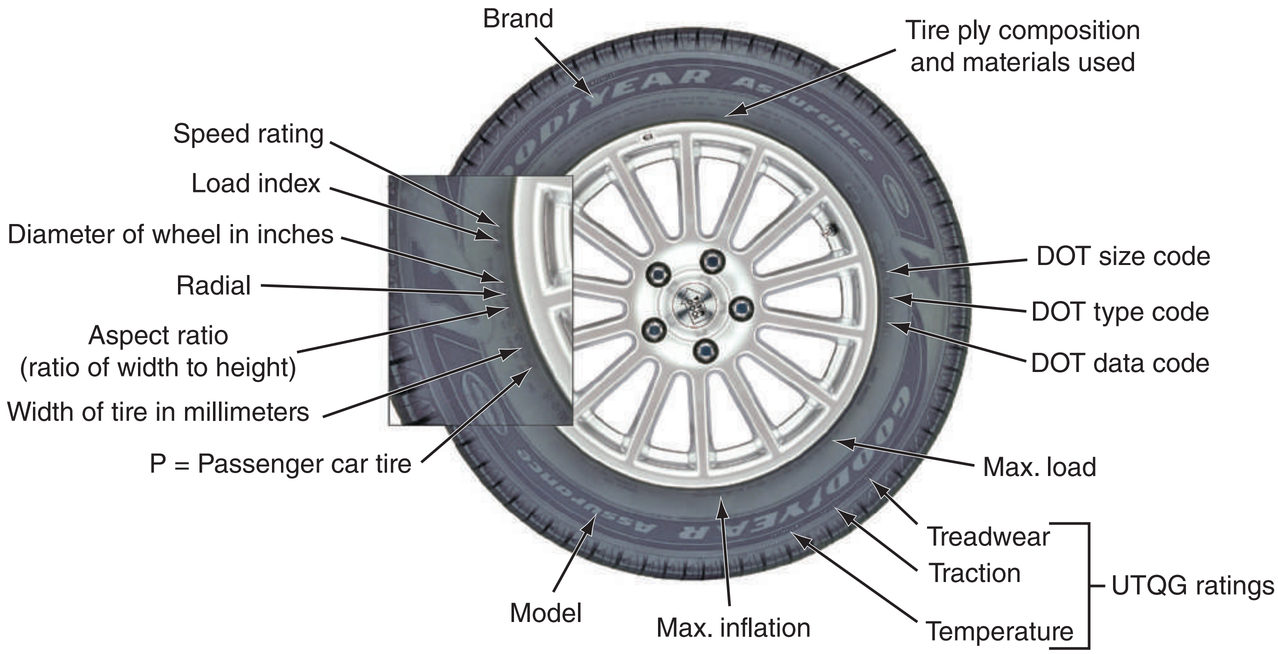

FIGURE 45–11 There is a lot of information about a tire on its sidewall.

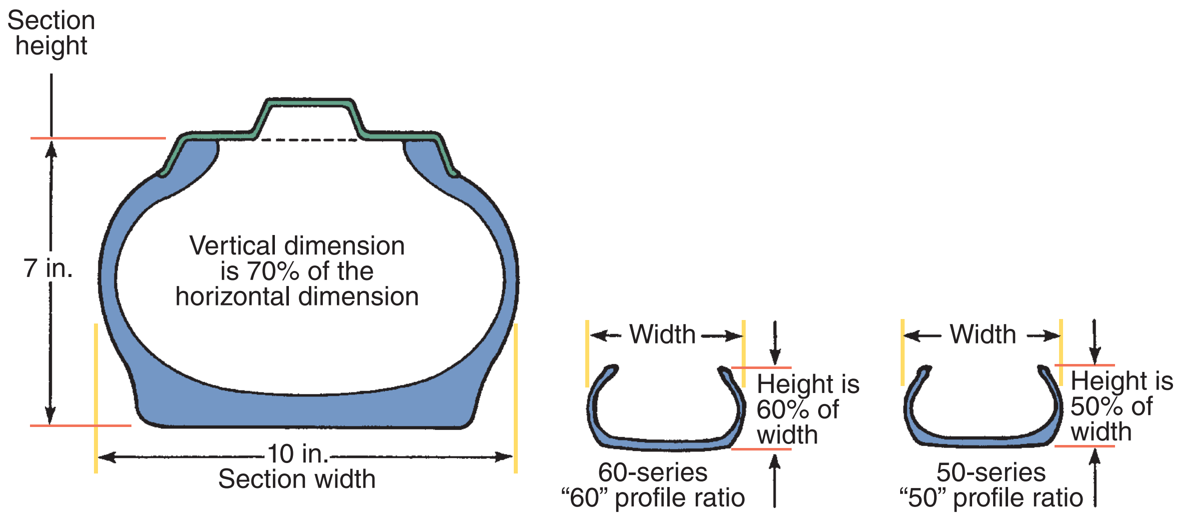

FIGURE 45–12 The aspect ratio (profile) of a tire is its cross-sectional height compared to its cross-sectional width expressed in a percentage.

height (from tread to bead) to its cross-sectional width (from sidewall to sidewall). In our example, the tire's height is equal to 65 percent of its width (the width equals 215 mm × 65 percent or 140 mm). The aspect ratio determines a tire's performance characteristics. Higher aspect ratios provide a softer ride because they will deflect more over irregular surfaces and under heavy loads. Shorter sidewall heights demand stiffer sidewalls. Therefore, tires with a low aspect ratio have a harsher ride. However, they provide a larger contact area with the road and therefore better traction.

For a tire rated as P215/65 **R**15 89H the *R* represents the basic ply construction of the tire. This letter can be an "R" for radial construction, a "B" for belted-bias construction, or a "D" for bias ply ("bias" means the plies are set diagonally or at a slant).

The diameter of the wheel is indicated by the *15* after the R. The diameter of the wheel for this tire is 15 inches. Wheel diameter is the height of the wheel from one end to the other.

Following the size notation is the load and speed ratings. These are expressed by a number and a letter; in this case the ratings are given as 89H. The *89* is the load index and the *H* is the speed rating.

The maximum load rating lists the maximum amount of weight the tire can carry at the recommended tire pressure. For bias tires, the load rating and the number of tread and sidewall plies are proportional. In most cases, the more plies a tire has, the more weight it can support. For modern radial tires, the higher the tire's load index number, the greater its load carrying capacity. The load ratings for passenger car and light truck tires range from 70 to 110. Following are some examples of load ratings and the weight they represent:

71 = 761 lb (345 kg)
79 = 963 lb (437 kg)
89 = 1,279 lb (580 kg)
99 = 1,709 lb (775 kg)
109 = 2,271 lb (1,030 kg)

So in our example, the tire can carry 1,279 lb (580 kg).

The speed rating indicates the maximum speed at which the tire should be used. In this case, the *H* means the tire has been tested to be safe at speeds up to 130 mph (210 km/h). The speed rating of a tire is really nothing more than an expression of how well the tire will withstand the temperatures of high speed. This does not necessarily mean that a high-speed-rated tire will perform better at low speeds than a lower-rated tire. Speed ratings apply only to properly maintained, and not overloaded, damaged, or patched tires.

Table 45–1 lists the various letters used to designate the speed rating of a tire and the maximum speed at which the tire was designed to safely operate. Driving a vehicle at speeds greater than the speed rating of the tires is risky. The heat generated can cause the tire to come apart. If this happens at high speeds, it will be close to impossible for the driver to maintain control of the vehicle.

Other Information

The sidewall of a tire also has a DOT safety code, tire identification or serial number, UTQG ratings, and maximum inflation values. The DOT code indicates that the tire has met all of the applicable safety standards established by the U.S. Department of Transportation (DOT). Next to the DOT code is a tire identification or serial number. This is a combination of numbers and letters that identify the tire manufacturer, where it was made, the tire design and size, and the week and year the tire was manufactured.

UTQG stands for Uniform Tire Quality Grading, a rating system developed by the DOT. This rating is comprised of three factors: tread wear, traction, and temperature resistance. All tires, except snow tires, have these ratings.

Tread Wear The tread wear grade is a rating based on a tire's wear rate when tested under controlled conditions on a specified government test track. Tread wear is listed as a number: The higher the number, the longer the tread will last. A rating of 100 is considered normal, whereas ratings lower than 100 mean poor tread wear. Ratings above 100 mean the tire has better-than-normal tread wear. These

ratings should be used to compare the anticipated wear of tires from the same manufacturer and not to compare wear between manufacturers.

Traction Tire traction ratings are based on a tire's ability to stop on wet concrete and asphalt. It is not an indication of how well a tire will handle. The traction rating is given as AA, A, B, or C. A tire rated as C will provide less traction than one rated with an A.

Temperature Resistance This rating is an indication of how well a tire will dissipate heat and how it works when it is heated. The temperature rating applies only to a properly inflated tire that is not overloaded. Heat builds up when a tire is underinflated or overloaded. Temperature also increases with excessive speeds. Temperature resistance rating is given as A, B, or C. A rating of C means the tire is acceptable. A tire with an A temperature rating will be able to withstand high temperatures better than one rated B or C.

Additional Ratings Some tires carry additional markings related to their intended service. An M&S or M+S designation means the tire has been rated by the manufacturer as suitable for mud and snow use. This is the designation for many all-season tires. Some tires may also have a mountain/snowflake symbol, which indicates that these tires are suitable for severe snow conditions; these are commonly called winter tires.

Maximum Cold Inflation and Load

The sidewalls of all passenger tires are marked to indicate the tires' maximum load capacity and maximum cold inflation pressure. It is important to remember that the maximum inflation number on a tire is its maximum inflation, not its recommended inflation. Tires should never be inflated beyond their maximum rating.

Tire Placard

The tire placard, or safety compliance certification label, is generally found on the driver's door jamb. This label may also be located in the glove box or on the fuel door. It includes recommended maximum vehicle load, tire size (including spare), and the *correct* cold tire inflation for each tire of the vehicle **(Figure 45–13)**. Never use this information for other cars.

As a general rule, tires should be replaced with tires of the same size and design specifications or an approved optional size as recommended by the auto or tire manufacturer. Also, always follow the manufacturer's recommendations for tire type, inflation pressures, and rotation patterns.

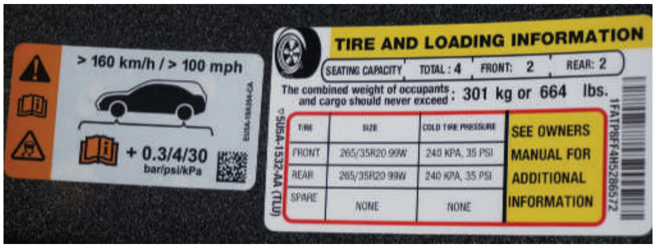

FIGURE 45–13 A tire placard on a door jamb.

SHOP TALK

Tires with a larger or smaller diameter than originally installed will affect the operation of the antilock brake system and the accuracy of the speedometer. It might be necessary to recalibrate the ABS and traction control computers and change the speedometer drive gears when tire size has been changed. Check the vehicle's service information for details.

Tire Care

To maximize tire performance, inspect for signs of improper inflation and uneven wear, which can indicate a need for balancing, rotation, or wheel alignment. Tires should also be checked frequently for cuts, stone bruises, abrasions, and blisters, and for objects that might have become imbedded in the tread. More frequent inspections are recommended when rapid or extreme temperature changes occur, or where road surfaces are rough or occasionally littered with debris.

To clean tires, use a mild soap and water solution only. Rinse thoroughly with clear water. Do not use any caustic solutions or abrasive materials. Never use steel wool or wire brushes. Avoid gasoline, paint thinner, and similar materials having a mineral oil base. These materials will cause premature drying of the tire's rubber. As the rubber dries, it gets harder and the tire will lose some of its performance characteristics.

GO TO Chapter 8 for more discussion on maintaining tires.

Inflation Pressure A properly inflated tire gives the best tire life, riding comfort, handling stability, and fuel economy. Keep in mind that it is the air pressure inside the tire that is actually supporting the weight of the vehicle. Too little air pressure can result in tire squeal, hard steering, excessive tire heat, abnormal tire wear, and increased fuel consumption by as much as 10 percent. An excessively low tire can cause severe and permanent damage to the sidewalls if driven on for even a short period of time. An underinflated tire shows maximum wear on the outside edges of the tread; there is little or no wear in the center **(Figure 45–14)**.

Conversely, an overinflated tire shows its wear in the center of the tread and little wear on the outside edges. Too much air can also cause a hard ride and tire bruising.

It is not unusual for a vehicle to specify different inflation pressure for the front and rear tires. Many inflation pressures listed for imported vehicles are given in kilopascals (kPa) rather than psi. **Table 45–2** converts kPa to psi.

SHOP TALK

The temperature of a tire affects its actual inflation. Pressure increases with an increase in temperature. The opposite is also true. Keep in mind that a 10 °F (5.5 °C) change in temperature will change the air pressure by 1 psi (6.9 kPa). Always adhere to the cold inflation pressures given on the tire placard.

SHOP TALK

Since 2010 in California, every vehicle under 10,000 pounds (4,536 km) GVW that enters a repair facility is to have the tire pressure checked and adjusted. In addition, the service must be documented and records kept for a minimum of three years.

Tire Rotation

Part of a preventive maintenance program is the rotation of the tires. Doing this on a regular basis can preserve balanced handling and traction and even out tire wear. Most manufacturers recommend this be done at least every 6,000 miles (9650 km). It is important to remember that tire rotation will not correct wear problems due to misalignment, worn mechanical parts, or incorrect inflation pressures.

The industry has described seven rotation patterns that cover the procedure for most cars and light trucks **(Figure 45–15)**.

Tread Wear

Most tires used today have built-in tread wear indicators (wear bars) to show when they need replacement. These indicators appear as ½-inch wide bands when the tire tread depth wears to $\frac{1}{16}$ inch (1.6 mm) **(Figure 45–16A)**. When the indicators

The front-to-rear (D) pattern may be used for vehicles equipped with the same-size directional wheels and/or tires. The side-to-side (E) pattern may be used for vehicles equipped with different-sized nondirectional tires and wheels on the front axle compared to the rear axle. appear in two or more adjacent grooves at three locations around the tire or when cord or fabric is exposed, tire replacement is recommended.

If the tires do not have tread wear indicators, a tread depth indicator **(Figure 45–16B)** quickly shows in 32nds of an inch how much tire tread is left. When only $^{2}/_{32}$ inch is left, it is time to replace a tire.

Proper wheel alignment allows the tires to roll straight without excessive tread wear. The wheels can go out of alignment from striking raised objects or potholes. Misalignment subjects the tires to uneven and/or irregular wear.

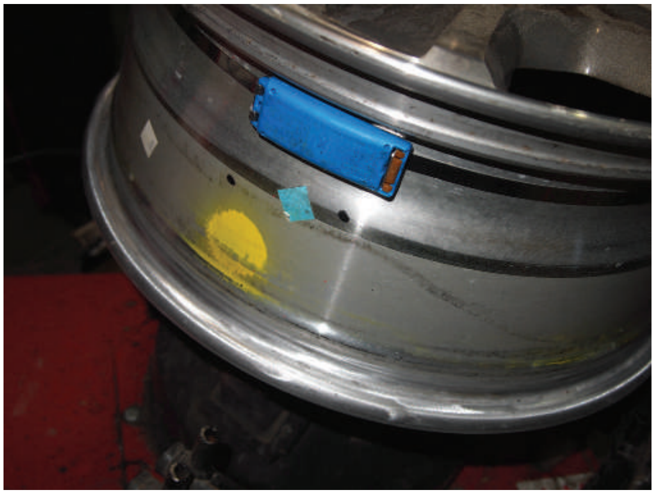
Tire Pressure Monitor (TPM) Systems

The U.S. DOT National Highway Traffic Safety Administration (NHTSA) has developed a federal motor vehicle safety standard that requires the installation of tire pressure monitoring (TPM) systems on all 2008 and newer passenger cars, trucks, multipurpose passenger vehicles, and buses with a gross vehicle weight rating of 10,000 pounds or less, except those vehicles with dual wheels on an axle. The monitoring systems must illuminate a warning light if one or more tires is at least 25 percent below the recommended cold-inflation pressure to warn the driver of an underinflated tire. As a result of this standard, two basic TPM designs are being used.

The most commonly used system is referred to as a direct system. In this system an air pressure sensor is strapped around the drop center of each wheel **(Figure 45–17A)**, or the sensor is attached to a special tire valve **(Figure 45–17B)**. The pressure sensor measures the tire's inflation pressure and relays this information to the vehicle via radio waves. These signals are picked up by a body-mounted antenna typically, the remote door lock receiver.



(A)

(B)

FIGURE 45–17 (A) A TPMS strapped to the inside of the wheel. (B) A tire pressure monitor and air valve assembly.

A central electronic control unit processes the signals from the four wheels and reports any variations to the system.

The tire pressure monitor (TPM) checks the inflation pressures in all four tires at frequent periodic intervals. The TPM sensors keep track of the tire pressures both when the vehicle is moving and when it is stationary. If the TPM detects enough change in any tire's inflation pressure, it responds by triggering a warning lamp on the instrument panel.

A typical **direct TPM** system has the following components:

- Tire pressure sensor and air valve. This may be a single unit, called a clamp-in sensor **(Figure 45–18A)** or the stem may be separate and replaceable **(Figure 45–18B)**. These are called snap-in sensors. Either type may be able to adjust the angle of the stem to the sensor, allowing them to be used in different wheel applications. The sensor measures tire pressure and temperature and transmits a signal and unique ID number for that particular sensor. Both types of sensors have a built-in battery that is not replaceable.
- Tire pressure warning antenna and receiver **(Figure 45–19)**. This unit receives and transmits the signals from the transmitters to the tire pressure warning control unit. The TPM receiver is often built into the remote keyless entry (RKE) receiver located in the driver's door though some vehicles use a dedicated TPM receiver.
- Tire pressure warning control unit. This unit receives the signal from the receiver. If the measured air pressure is equal to or lower than a specified value, this unit transmits a signal, causing the air pressure warning light to illuminate.
- Tire pressure warning light. Located in the instrument cluster, this unit informs the driver of low tire pressure or a problem in the system.
- Tire pressure warning reset switch. This unit is used after setting the tire pressure, or after sensor, tire, or wheel replacement. It is used to allow the control unit to relearn the system.

In an attempt to meet the TPM standard without the cost of a direct system, some manufacturers use an indirect system. These systems do not use pressure sensors; rather they rely on the inputs from wheel-speed sensors. These signals have been used for ABS or other systems. With **indirect TPM**, the PCM is reprogrammed to use those signals to identify when a tire has lost air pressure. Indirect systems are also used on some older vehicles with run-flat tires. This was necessary because run-flat

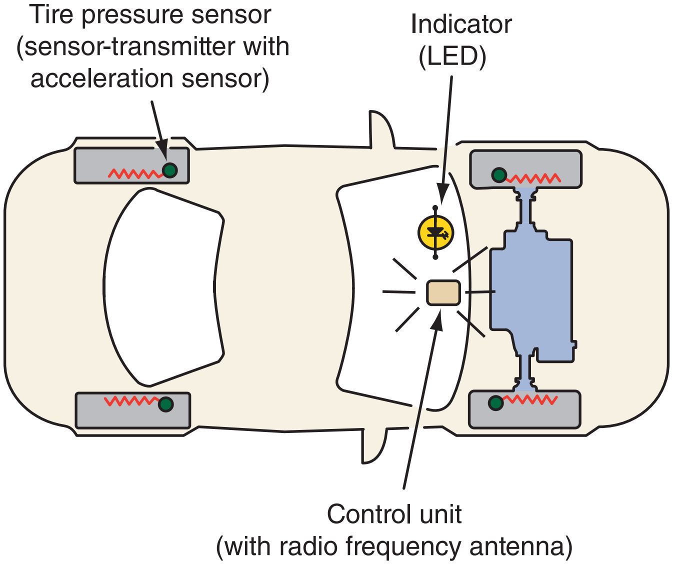

FIGURE 45-19 Basic components for a direct TPM system.

tires without air appear normal. The driver needs to be alerted to the loss of air.

The input signals from the wheel-speed sensors are used to compare the rotational speeds of the four tires. When a tire loses or gains air pressure, it will roll at a slightly different number of revolutions per mile than the other three tires. When the computer senses this difference, a warning lamp will light.

Indirect systems are not as effective as direct systems, however. These systems cannot tell the driver which tire has low pressure. They also are not capable of informing the driver when all four tires are losing air pressure. This commonly happens when the outside temperature drops.

Warning System The TPM warning system can vary from a warning lamp to a graphic display that shows which tire is low on pressure. Many systems allow the driver to monitor the current air pressure of each tire. If the PCM detects a problem with the TPM system, a warning lamp or message will appear in the instrument cluster. After tires have been rotated or replaced, the system may need to relearn tire position. During this time, a message or warning lamp may be illuminated. Once the relearning process is completed, the message will turn off.

If the system is working correctly, the TPM lamp and the low tire pressure lamp should illuminate for about 2 seconds when the ignition is turned on. If the lamps do not turn off, there is a problem in the system. Typically, low tire pressure keeps the warning lamp on after the vehicle is started. A problem with the system, such as failed sensor, will cause the light to flash. The system will typically set a DTC when there is a problem with the system or when it detects low pressure in any of the four tires.

Testing a TPM System

The TPM system in most vehicles is tied directly to the PCM; therefore, faults cause DTCs to set. TPM system data can often be monitored and DTCs retrieved with a scan tool **(Figure 45–20)**. Special tools are required to accurately test the problem sensor(s). A TPM sensor tool is a wireless tool that may be used with a scan tool for diagnosing sensors and allowing the system to relearn when a part has been replaced. Some TPM tools can plug into the DLC and perform a system relearn after tire service, eliminating the need for using a scan tool.

The TPM sensor tester is used to reset the system, which may be needed after tires are rotated, tires or wheels are replaced, repairs are made to the system, and when the vehicle's battery is low or replaced. The tester activates the sensors and the transmitted data from them can be observed. Most systems require placing the tool near the sensor and then activating the sensor via the tool **(Figure 45–21)**. The sensor then broadcasts information such as the sensor ID,

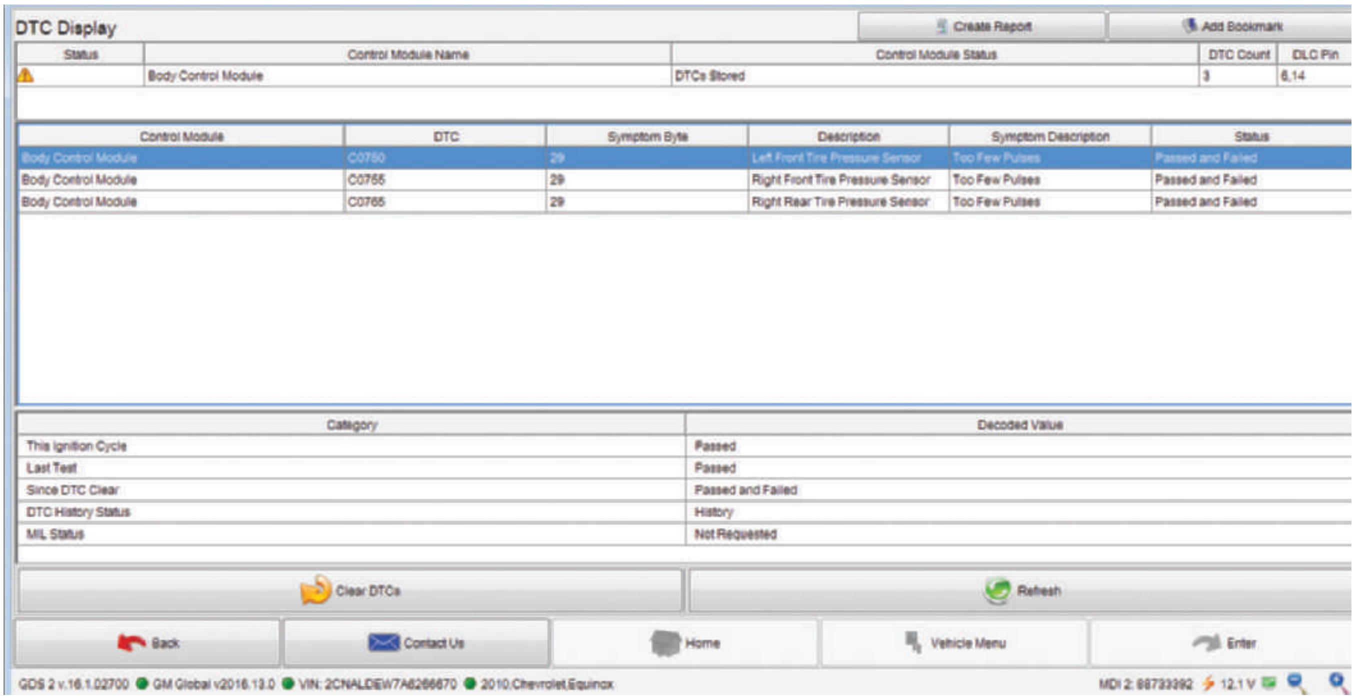

FIGURE 45–20 TPM data displayed on a scan tool.

FIGURE 45–21 A TPM tester.

tire pressure and temperature, and battery information. If a sensor fails to communicate, the internal battery may be dead or the sensor is faulty. Any problem with the sensor requires sensor replacement.

TPMS Service

TPMS service can range from simply checking and setting tire pressure to replacing sensors and correcting faults with the receiver, wiring, or network. Before working on the tires or TPM system, verify system operation by observing the TPM warning light on the dash. Make sure the light comes on during the key-on bulb check and goes out once the engine starts. If the TPM light remains on or flashes, test the sensors and system to determine the fault before continuing. This approach is called “test before you touch” and has been adopted by the auto repair industry as a way to check TPM system condition before doing any tire service, even adjusting air pressure. Any problems with the TPM need to be documented on the repair order and addressed with the customer.

CUSTOMER CARE

A customer may ask about not replacing TPM sensors that have stopped working or removing them when installing new tires. Because the TPM system is a mandated safety system installed from the factory, it is not up to the shop or the technician to decide whether or not the sensors should be installed. Removing or bypassing any type of safety system on a vehicle is unwise and can have legal consequences.

Because the TPM systems are mandated safety equipment, it is illegal for technicians and shops to disable or tamper with its operation. If the TPM system is inoperative when the vehicle comes into the shop, such as from dead sensor batteries, the customer can refuse to replace the faulty sensors. The RO should thoroughly document the condition, and you should have the customer sign off that the system in inoperative.

If a vehicle is in for service, such as tire replacement, and a sensor becomes damaged, it will need to be replaced to keep the system operational. Disabling the TPMS and putting the vehicle back out on the road could have serious legal consequences if an accident were to occur due to an inflation issue.

The TPM system usually requires a relearn after work is performed, including setting tire pressure, rotating the tires, and replacing a sensor. Before performing a tire rotation on a vehicle with a direct TPM system, check the service information for any special procedures that need to be followed to perform the relearn. On many indirect systems, pressing the TPM Learn button places the vehicle into learn mode. After driving for several minutes, the system learns tire rotation speeds and infers each tire’s pressure. Activating learn mode on direct systems vary on the year, make, and model of vehicle. **Table 45–3** shows common TPM relearn procedures.

A fault in the TPM system will set DTCs in the computer system and cause the TPMS warning light to flash and/or stay on as well. Nonfunctioning pressure sensors are the most common reason for failures. These sensors cannot be serviced and must be replaced when faulty or when the battery is too weak to broadcast the signal. Most manufacturers recommend replacing the sensors when the tires are replaced or every five to seven years.

Replacing a TPM Sensor

Once you have confirmed a sensor needs replacement, dismount the tire from the wheel. Some vehicles use a band clamp sensor. To replace this type,

remove the clip holding the sensor to the band and rotate the sensor from the clamp. For clamp-in sensors, remove the outer cap and pull the sensor out from the valve stem hole in the rim. Snap-in sensors require removing the screw holding the stem to the sensor. Apply tire lubricant if indicated by the sensor manufacturer and install the new sensor on the wheel. With both types of stem sensors, it is important that they are properly installed and torqued. Clamp-in sensors require a seal between the stem and the wheel and that the cap be torqued, typically to around 30 to 80 in.-lbs. Snap-in stems are torqued using a special torque wrench screwdriver for TPM sensors. Valve cores are also torqued with a special tool. With both sensor types, do not guess when tightening, check the

torque specifications and use the proper tools **(Figure 45–22)** or you can damage the sensors.

Replacement sensors can be either OE or aftermarket types, which determines how the new sensor is programed to the vehicle. For some systems or sensors, you need to locate and record the old sensor ID number and use it for the new sensor. This is called sensor cloning. Other systems allow the new sensor ID numbers to register into the system. Refer to the service information for which type of sensor is used and how new sensors are programed.

New sensors are shipped turned off or in a shipping mode. To program the new sensor to the vehicle, activate the TPM learn mode. This may be done through the driver information center **(Figure 45–23)**,

the key fob, TPM tool, or scan tool. Activate each sensor per the manufacturer's procedures and verify proper system operation once complete.

Tire/Wheel Runout

A tire that is off center or egg shaped is said to run out. This is known as **radial runout** or eccentricity. One that wobbles side-to-side is said to have **lateral runout**. If a tire with some built-in runout is mismatched with a wheel's runout, the resulting total runout can exceed the ability of the balance weights to correct the problem. For this reason, part of a tire/wheel inspection should be for excessive runout. Sometimes tires or wheels can be remounted to lessen or correct runout problems.

To avoid false readings caused by temporary flat spots in the tires, check runout only after the vehicle has been driven. Visually inspect the tire for abnormal bulges or distortions. The extent of runout should be measured with a dial indicator. All measurements should be made on the vehicle with the tires inflated to recommended load inflation pressures and with the wheel bearing adjusted to specification.

Measure tire radial runout at the center and outside ribs of the tread face. Measure tire lateral runout just above the buffing rib on the sidewall **(Figure 45–24)**. Mark the high points of lateral and radial runout for future references. On radial ply tires, radial runout must not exceed 0.081 inch (2.06 mm) and lateral runout must not exceed 0.099 inch (2.51 mm).

If the total radial or lateral runout of the tire exceeds the specified limits, it is necessary to check wheel runout to determine whether the wheel or tire is at fault. Wheel radial runout is measured at the wheel rim just inside the wheel cover retaining nibs. Wheel lateral runout is measured at the wheel rim bead flange just inside the curved lip of the flange. Wheel radial runout should not exceed 0.035 inch (0.89 mm) and wheel lateral runout should not exceed 0.040 inch (1.02 mm). Mark the high points of radial and lateral runout for future reference.

If the total tire runout, either lateral or radial, exceeds the specified limit but wheel runout is within the specified limit, it might be possible to reduce runout to an acceptable level. This is done by changing the position of the tire on the wheel so that the previously marked high points are 180 degrees apart. Many computer wheel balancing machines can detect wheel and tire runout and determine the best way to remount the tire on the wheel to reduce total runout.

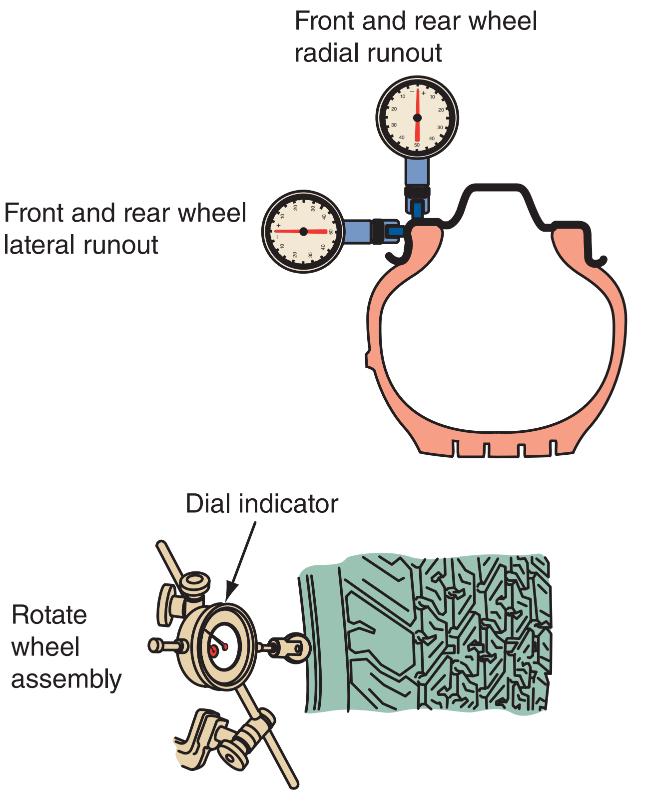

FIGURE 45–24 Checking wheel runout.

Axle flange runout can cause vibration concerns similar to those caused by wheel and tire runout. The axle flange can be damaged or bent by impacts with curbs and cause the wheel to wobble when driving. Use a dial indicator to measure runout at the flange **(Figure 45–25)** and compare to specifications.

Tire Pull

It is not uncommon for a tire to cause a pull to one side when driving. This is caused by conicity, meaning the tire has a cone shape. As the tire rotates, it tries to go in the direction of the narrow end of the cone shape, pulling the vehicle either left or right. Unfortunately, this problem occurs during tire construction and cannot be fixed. Depending on the severity of the conicity problem, the tire, if installed on the rear of the vehicle, may not cause a pull until it is moved to the front of the vehicle during a tire rotation. If this occurs, the customer may return to the shop complaining the car pulls to one side since the tires were rotated. To check if conicity is the cause, switch the front tires from side-to-side and test drive the vehicle. If the pull goes away or pulls in the other direction, conicity is the problem.

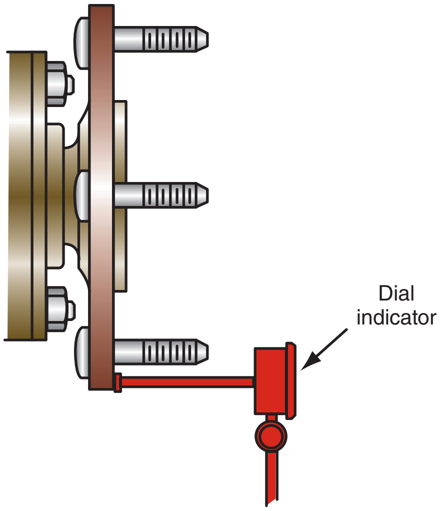

FIGURE 45–25 Measuring axle flange runout.

Tire Replacement

Tires should be replaced when they are worn or heavily damaged. In addition, because modern tires last much longer than those even 20 years ago, tire age needs to be considered. Tires, especially those that remain outside all year, are subject to dry rot and cracking. Over time this weakens the tire and can lead to tire failure. Although there is not a current replacement age requirement in the United States, many tire and rubber manufacturers recommend tire replacement based on age alone at 6 to 10 years. Tires that reach 6 years of service should be very carefully inspected for wear, damage, and rot. Once a tire reaches 10 years, it should be replaced.

Replacement tires should match the tires that were on the vehicle originally. This is the preferred choice unless a change in appearance or handling is desired. Vehicle manufacturers know how important the right tire is. They spend a great deal of time developing a suspension system that works in the way they believe it should. Part of that development is tire design. However, the tire choice by manufacturers is a compromise—a compromise between characteristics. Manufacturers choose the characteristics they believe owners of that model vehicle want. If the owner is happy with the vehicle, recommend that the replacement tires match the ones the vehicle was originally sold with. When replacing tires, installing tires that do not meet the requirements of the OE tires could place you in legal trouble. If a tire does not meet the OE specifications for the vehicle, such as for load capacity or speed rating, and the

replacement tire fails, you could face legal consequences for installing a sub-standard tire.

Replacing One Tire

In some cases, only one tire needs to be replaced. The usual causes of this are that the tire was damaged due to an accident, a road hazard, or vandalism. Replacing one tire is recommended only if the other tires have a satisfactory amount of tread left. Make sure the replacement tire is the same brand, type, size, and speed rating as the other tires. If the replacement tire is different from the rest, the vehicle can exhibit unsafe handling problems. Also, the replacement tire should have a similar tread design as the remaining tires. This helps reduce noise and other issues that can be caused by dissimilar tread designs. The replacement tire should be mounted on the rear axle and the tire (of the remaining three) with the most tread depth should be mounted on the opposite side of the axle.

Replacing Two Tires

If there is a need to replace two tires and the other two have good treads, the replacement pair should be mounted on the rear axle. The replacement tires should match the remaining pair of tires as closely as possible.

Four-Wheel and All-Wheel Drive Vehicles

Because of the increased popularity of small SUVs and other vehicles using all-wheel drive, replacing tires as a set of four is now recommended. These all-wheel drive systems use a center differential or viscous clutch to apply power to a set of wheels when there is a speed difference between the front and rear wheels. If only a pair of tires is replaced, this leaves a set of worn tires on one axle. The worn tires will have a slightly smaller diameter than the new tires are on the other axle. Even this small amount of size difference can cause a speed difference between the front and rear tires. The difference in size creates a difference in wheel rotation speeds, which can damage the differential or viscous clutch over prolonged use.

Changing Tire and/or Wheel Size

An owner may want more emphasis on handling or fuel economy and may desire a different type of tire and/or wheel. There are several other factors that may dictate a change in tire size, and the customer may come to you for advice. Perhaps one of the most important considerations is that the tire must be able to carry the weight of the vehicle. The load-carrying capacity of a tire must be the same as or higher than the OEM tire. Changing tires from one aspect ratio to another also changes the sectional width, which relates to the load-carrying capacity of the tire.

Most tire width changes affect the overall diameter of the tire. A change in the tire's outside diameter will cause a change in the overall gear ratio and will affect the accuracy of the speedometer and odometer. A change in tire diameter or aspect ratio may also affect overall driveability. This is due to false readings from the vehicle or wheel-speed sensors. On passenger cars and mini-vans, a 3 percent or less change in tire diameter is acceptable. Most SUVs and pickups can handle a change as much as 15 percent. The overall diameter of a tire can be calculated.

A vehicle may have the ability to change the tire size that is programmed into the on-board computer system. Typically the options to change the tire size is one of the sizes offered as an option from the vehicle manufacturer **(Figure 45–26)**.

Plus Sizing A way to change the contact area of a tire without seriously affecting its overall diameter is using the plus sizing system. This system is based on the overall diameters of a combination of different-sized tires and wheels. The system requires much research but it is the best way to achieve the

FIGURE 45-26 Changing wheel and tire size with a scan tool.

desired results. For example, the customer wants to have a wider tread area **(Figure 45–27)**. The OEM tire was a 195/75-14 tire mounted on a 14 × 6 inch wheel. The overall diameter of this assembly is 25.5 inches (647.7 mm). There are three available wheel/tire combinations that closely match that diameter. If a 205/65-15 tire is mounted on a 15 × 7 inch wheel, the width increases by 0.39 inches (10 mm), whereas the diameter stays the same. If a 16 × 7.5 inch wheel is used along with a 225/55-16 tire, the width increases by 1.18 inches (30 mm) and the overall diameter increases by only 0.2 inch (5.1 mm). Going even wider, if a 235/45-17 tire is mounted on a 17 × 8 inch wheel, the tire's width increases by 1.57 inches (40 mm) and the overall diameter decreases by 0.2 inch (5.1 mm). Although the latter two changes do not match the OEM diameter, they are certainly within the 3 percent rule.

Additional Points Here are some additional important points to consider:

- Handling improvement typically comes from more tire contact on the road, and fuel economy increases with less.
- Increasing tread width and tire contact can affect steering effort as more tire is in contact with the road surface.
- Tires of different sizes, constructions, and wear may affect handling, stability, and fuel economy.
- Too wide of a tire may rub against the body or suspension.
- Radial tires should never be mixed with another type of tire on the same vehicle.
- All tires on the vehicle should be the same size, construction, tread design, and speed rating unless the vehicle was otherwise equipped by the OEM.
- Tires should be replaced with ones of the same or higher speed rating. Speed ratings should not be downgrades from original equipment ratings.
- A hard tread will provide long wear and low rolling resistance but will also have poorer traction.
- An aggressive tread pattern may provide resistance to hydroplaning or better traction in the snow, but they are noisier on dry surfaces.
- A tire with stiff sidewalls will increase high-speed stability and improved handling, but it will make the overall ride rougher.
- A replacement rim should provide the same overall tire diameter as the original.
- A narrower rim pulls the beads of the tire closer together, causing the sidewalls to curve. This allows the sidewalls to flex more, which results in a softer ride but reduces tire life.
- A wide rim increases the distance between the beads, which stiffens the sidewalls and provides a harsher ride and shorter tire life. However, it will improve the handling of the vehicle.
- A replacement tire should have, at minimum, the qualities of the tires installed when the vehicle was new. Replacing tires with ones with a reduced load capacity, traction, or temperature rating is not recommended.

Calculating Tire Dimensions When replacing tires with other than the original tire size, you may need to calculate the dimensions of a desired replacement tire. Like everything else, there are formulas to make these calculations.

To determine the section height of a tire, multiply its aspect ratio by the sectional width.

$$\text{Width} \times \text{Aspect Ratio} = \text{Section Height}$$

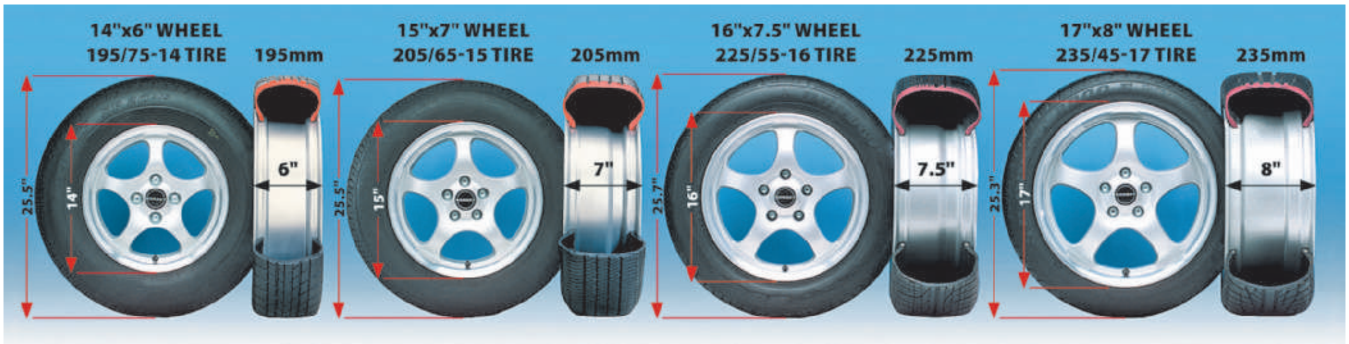

FIGURE 45–27 The effects of plus sizing.

To determine the overall diameter of a tire, multiply the sectional height by 2 (this is called the combined sectional height because there are two), then add the diameter of the wheel.

Combined Section Height (Sectional Height × 2) + Wheel Diameter = Tire Diameter

Tire/Wheel Assembly Service

For most tire/wheel service, the assembly must first be removed from the vehicle. The wheel and the tire must be separated whenever tires are replaced or repaired. The wheel and tire mount on the hub flange, which may be on the end of an axle or part of a brake rotor or drum. The wheel is held against the hub and drum or rotor by the wheel nuts or bolts. Most cars and trucks use lug nuts that thread onto studs. However, many European cars use wheel bolts that thread into holes in the hub flange to secure the wheels in place.

Tire Repair

The most common tire problem besides wear is a puncture. When properly repaired, the tire can be put back in service without the fear of an air leak recurring. Punctures in the tread area are the only ones that should be repaired or even attempted to be repaired. Never attempt to service punctures in the tire's shoulders or sidewalls. In addition, do not service any tire that has sustained the following damage:

- Bulges or blisters
- Ply separation
- Broken or cracked beads
- Fabric cracks or cuts
- Wear to the fabric or visible wear indicators
- Punctures larger than ¼-inch (6 mm) diameter

Some car owners attempt to seal punctures with tire sealants. These sealants are injected into the tire through the valve stem. Sometimes the chemicals in the sealant do a great job sealing the hole, other times they fail. The sealants should never be used for and will not work on sidewall punctures. Some of the sealants are very flammable and carry a warning that the tire should be marked so that the next technician knows the sealant has been used.

Sealants may interfere with the operation of TPM sensors. If tire sealant has been used, the customer should be notified that damage to the sensor may occur and it may need to be replaced.

Warning! Tire sealants injected through the valve stem can produce wheel rust and tire imbalance.

To locate a puncture in a tire, inflate it to the maximum inflation pressure indicated on its sidewall. Then submerge the tire/wheel assembly in a tank of water or spray it with a soapy water solution. Bubbles will identify the location of any air leakage.

Mark the location of the leak with a tire crayon so it can be easily found once the tire is removed from the wheel. Also use the crayon to mark the location of the valve stem so that original tire and wheel balance can be maintained after the tire is put back on the wheel.

The proper procedure for dismounting and remounting a tire is illustrated in Photo Sequence 41. Do not use hand tools or tire irons alone to change a tire because they might damage the beads or wheel rim. When mounting or dismounting tires on vehicles using aluminum or wire spoke wheels, it is recommended that the tire changer manufacturer be contacted about the accessories that are required to protect the wheel's finish.

Warning! Once a tire puncture has been repaired, many tire manufacturers state that the tire no longer retains its speed rating. This is because the puncture compromises the tire and could ultimately fail under the stress of high-speed driving. Because of this, the work order must be noted and the customer be informed that the speed rating is no longer applicable to the repaired tire.

TPM Sensors

If the wheel/tire assembly has a direct TPM system, the sensor can be removed after the air pressure has been released from the tire. This should be done before the tire is removed from the rim. Unbolt the air valve assembly and allow it to drop into the tire. Before servicing the tire or wheel, remove the

sensor. After tire and/or wheel repairs have been made, install the sensor with a new rubber O-ring or seal and aluminum retaining nut. The retaining nut must be torqued to specifications.

Repair Methods

Once the tire is off the wheel and the cause of the puncture is removed and the location marked, the tire can be repaired from the inside using a service plug and a vulcanized patch. Although the repair kit's instructions should always be followed, there are some general guidelines that help make a good, permanent patch of the puncture. The following methods are the most common methods used to repair a tire.

Plug Repair The head-type plug is commonly used. A plug that is slightly larger than the size of the puncture is inserted into the hole from the inside of the tire with an insertion tool. Before doing this, insert the plug into the eye of the tool and coat the hole, plug, and tool with vulcanizing fluid. Sealing the puncture with a plug from the outside of the tire is not a proper repair.

CUSTOMER CARE

The repair of a Michelin PAX system requires special equipment, replacement parts, and specialized training. If you attempt to repair one of these systems without the necessary equipments, parts, and training, the tire warranty will become void. Make sure your customer understands this. Also, the use of plugs and/or sealants to repair the tire will void the warranty.

While holding and stretching the long end of the plug, insert it into the hole. The plug must extend above both the tread and inner liner surface. If the plug pops through, throw it away and insert a new plug. Once the plug is in place, remove the tool and trim off the plug $\frac{1}{32}$ inch (0.7 mm) above the inner surface. Be careful not to pull on the plug while cutting it.

Cold Patch-Plug Repair To properly repair a puncture, a one piece patch-plug or stem patch is used. This type of repair requires removing the tire from the wheel to inspect for internal damage. A tire that has been driven on flat will show obvious damage once removed **(Figure 45–28)**. This tire needs to be replaced and is dangerous if put back on the road due to the damage to the sidewalls. Removing the tire is the only way to check for this type of damage.

Remove the item that punctured the tire and ream the hole with a carbide cutting tool and drill. Once the tire is dismounted, buff the liner to prepare the surface. Clean and apply rubber cement and let it dry. Next, carefully remove the backing from the patch. Center the patch base over the punctured area and pull the plug through the puncture and seat the patch. Run a stitching tool over the patch to help bind it to the tire.

Warning! When repairing radial tires, use only a patch specially approved for that application. Some radial patches have arrows that must be lined up parallel to the radial plies.

Hot Patch Repair A hot tire patch application is similar to a cold patch. The difference is that the hot

Dismounting and Mounting a Tire on a Wheel Assembly

P41-1 Dismounting the tire from the wheel begins with releasing the air, removing the valve stem core, and unseating the tire from its rim. The machine does the unseating. The technician merely guides the operating lever.

P41-2 Once both sides of the tire are unseated, place the tire and wheel onto the machine. Then depress the pedal that clamps the wheel to the tire machine.

P41-3 Lower the machine's arm into position on the tire and wheel assembly.

P41-4 Insert the tire iron between the upper bead of the tire and the wheel. Depress the pedal that causes the wheel to rotate. Do the same with the lower bead.

P41-5 After the tire is totally free from the rim, remove the tire.

P41-6 Prepare the wheel for the mounting of the tire by using a wire brush to remove all dirt and rust from the sealing surface. Apply rubber compound to the bead area of the tire.

P41-7 Place the tire onto the wheel and lower the arm into place. As the machine rotates the wheel, the arm will force the tire over the rim. After the tire is completely over the rim, install the air ring over the tire. Activate it to seat the tire against the wheel.

patch is clamped over the puncture and heat is applied to the patch to make it adhere.

Mounting Run-Flat Tires

Mounting and dismounting a run-flat tire requires patience and skill. Most shops have rim-clamp tire changers. Some of these use rollers to loosen the beads, whereas others have side-shovel bead looseners. As the tire revolves on the changer, the rollers automatically loosen the beads. When using side-shovel bead looseners, the tire must be manually placed into position, rotated on the changer, and flipped. Roller bead looseners are preferred for run-flat tires.

The bead looseners must be positioned on the sidewall near the bead. If the loosener is placed too far away from the bead, it may damage the sidewall inserts in the tire. The rotation of the bead loosener should begin with the bead on the back of the tire and only be inserted enough to free the bead from the wheel. Tire lubricant should be applied to the tire and wheel as the bead moves away from the rim. The process is then repeated on the front side of the tire until the outside bead is loose. Care should be taken not to damage the TPMS sensor or the inner wheel ring (if so equipped). The tire should then be removed from the wheel, following the instructions of the tire changer.

Tire Recycling

When a tire is damaged or badly worn, it should be replaced and the old tires be disposed of properly. Used tires should never be just thrown away. Due to their construction, they present many environmental hazards if not disposed of properly. In fact it is against the law to add them to the trash and send them to a landfill. Old, used tires can trap methane gas. The gas can then leak through landfill liners and pollute the soil and ground water associated with the landfill. Tires can also serve as a breeding ground for disease-carrying organisms, particularly mosquitoes. Tires disposed of improperly also present a fire risk. Tire fires burn very hot and are extremely difficult to extinguish. Also, in the extreme heat of the fire, the tires can melt into an oily substance. This oily substance can run off and contaminate the ground and nearby surface water.

Proper disposal of tires includes sending them to a recycling plant. The tires' rubber is used to produce asphalt, shoes, playground cover, floor mats, and many other rubber products. Old tires can also be used to make a tire-derived fuel, or TDF, which produces a higher amount of energy than either oil or coal. The non-rubber portions of a tire are also recycled. For example, the steel beads are processed and used by steel mills to produce new steel.

Wheel Inspection

The wheels should be carefully inspected each time a tire is to be mounted on it. The major causes of wheel failure are improper maintenance, overloading, age, and accidents, including pothole damage. The use of low-profile tires often increases the risk of wheel damage as the short sidewalls absorb less of the road shock. Wheels must be replaced when they are bent, dented, or heavily rusted; have leaks, cracks or elongated bolt holes; and have excessive lateral or radial runout. Wheels with a lateral or radial runout greater than specifications can cause high-speed vibrations. Wobble or shimmy caused by a damaged wheel eventually damages the wheel bearings. Stones wedged between the wheel and disc brake rotor or drum can unbalance the wheel.

Inflation

After the tire is mounted to the wheel, inflate the tires to the recommended pressure. Also check to see if any air is leaking from the beads or the point of repair.

Nitrogen Tire Inflation Many tire experts recommend that tires be filled with nitrogen rather than compressed air. Other experts say there is no need

SHOP TALK

When installing new tires, always install new air valve stems. The life of tire rubber is close to the life of the valve stem rubber. Most stems are the snap-in type. These are installed from inside the wheel with a pulling tool. Make sure that the stem is properly seated. Another style of stem has a retaining nut that must be removed when pulling off the old stem. Be sure to completely tighten the new nut. Vehicles equipped with TPM sensors should also have the sensors replaced when new tires are installed.

to do this if owners watch the air pressure in their vehicle's tires. The idea behind using nitrogen is simple: Nitrogen molecules are larger than air molecules. Therefore, it is less likely to leak out of a tire. Those in favor of using nitrogen claim that nitrogen-filled tires stay inflated about three times longer than air-filled tires. Nitrogen also helps keep tires cooler while traveling on the highway. This means the air pressure stays more constant and is less likely to leak out. The supposed result of these advantages is safer and longer lasting tires. The idea of using nitrogen in tires is not new. Race cars, commercial airliners, and trucks have used nitrogen-filled tires for many years.

Nitrogen inflation requires a nitrogen filling station **(Figure 45–29)**. Typically, a fill/purge cycle fills the tire, purges the air and refills the tire with nitrogen until the desired amount of nitrogen is reached. Once a tire is filled with nitrogen, a green valve stem cap is installed to alert others to refill the tire with nitrogen only. However, an owner may refill a tire with compressed air if the tire is severely deflated, but that tire should be refilled with nitrogen shortly afterward.

FIGURE 45-29 A nitrogen filling unit.

Installation of Tire/Wheel Assembly on the Vehicle

Before reinstalling a tire/wheel assembly on a vehicle, inspect the wheel bearings as described later in this chapter. Sometimes a wheel rusts or corrodes to the hub flange. If necessary, clean the axle/rotor flange and wheel center bore with a wire brush or steel wool. Then coat the axle pilot flange with disc brake caliper slide grease or an equivalent.

Place the wheel on the hub. Make sure the wheel is seated on the hub. A common mounting problem is caused by improperly positioning the wheel on the wheel hub or by improperly tightening the lug nuts. If the wheel uses a hub flange adaptor, make sure it is installed so the wheel properly centers on the flange **(Figure 45–30)**.

Install the locking wheel cover pedestal (if used) and lug nuts, and tighten them alternately to draw the wheel evenly against the hub. They should be tightened to a specified torque and sequence **(Figure 45–31)** to avoid distortion. The best way to do this is to snug up the lug nuts, then use a torque wrench for the final tightening. Loose lug nuts can cause shimmy and vibration and can also distort the stud holes in the wheels. The worst case is when the wheel comes off while the vehicle is being driven. Go over each lug twice with the torque wrench to be sure each is torqued to specification. Once torqued, check and adjust the air pressure in all tires.

FIGURE 45-30 An aftermarket wheel with a hub adaptor ring.

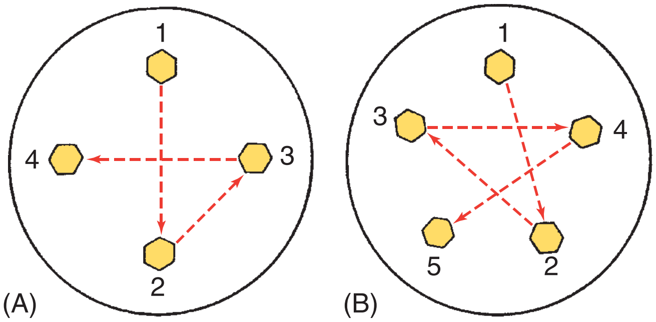

FIGURE 45-31 The lug nut tightening sequence for (A) a four-lug wheel and (B) a five-lug wheel.

Warning! Overtorqueing and uneven tightening of the lug nuts are a common cause of disc brake rotor distortion. Also, an overtorqued lug distorts the threads of the lug and could lead to premature failure. Undertorqueing the lug nuts could cause the wheel and tire to come off as the vehicle is being driven.

Tire/Wheel Balance

An out-of-balance condition can cause steering wheel shimmy and vibrations that can be felt throughout the vehicle. These vibrations are typically felt between 50 and 70 mph (81–113 km/h). Out-of-balance problems can also cause increased wear on the ball joints, as well as deterioration of shock absorbers and other suspension components.

Should an inspection show uneven or irregular tire wear, wheel alignment and balance service is a must. Wheel balancing distributes weights along the wheel rim, which counteract heavy spots in the wheels and tires and allow them to roll smoothly without vibration. The wheel weights are adhered to the wheel or are clipped over the edge of the wheel's rim. There are two types of wheel imbalance: static and dynamic.

Static Balance **Static balance** is the equal distribution of weight around the wheel. Wheels that are statically unbalanced cause a bouncing action called **wheel tramp**. This condition eventually causes uneven tire wear. As the name implies, static balance means balancing a wheel at rest. This is done by adding a compensating weight. A statically unbalanced wheel tends to rotate by itself until the heavy portion is down. A bubble balancer can be used to

FIGURE 45-32 A typical wheel weight attached to a wheel.

statically balance a tire and wheel. When it is placed on the balancer, any imbalance moves the bubble off center.

Many equipment manufacturers recommend static balancing a wheel at equal distances from the center of the light area. Balance weights are normally hammered on with their holding tabs between the tire bead and rim **(Figure 45–32)**. Wheel weights are not normally hammered onto alloy or mag wheels; rather, special tape weights are adhered to the wheels to balance them.

Dynamic Balance **Dynamic balance** is the equal distribution of weight on each side of the centerline. When the balanced tire spins, there is no tendency for the assembly to move from side-to-side. Wheels that are dynamically unbalanced can cause **wheel shimmy** and a wear pattern **(Figure 45–33)**. Dynamic balance, simply stated, means balancing a wheel in motion. Once a wheel starts to rotate and is in motion, the static weights try to reach the true plane of rotation of the wheel because of the action of centrifugal force. In an attempt to reach the true plane of rotation when there is an imbalance, the static weights force the spindle to one side.

At 180 degrees of wheel rotation, static weights kick the spindle in the opposite direction. The resultant side thrusts cause the wheel assembly to wobble or wiggle. When the imbalance is severe enough, as already mentioned, it causes vibration and front-wheel shimmy.

To correct dynamic unbalance, equal weights are placed 180 degrees opposite each other, one on the

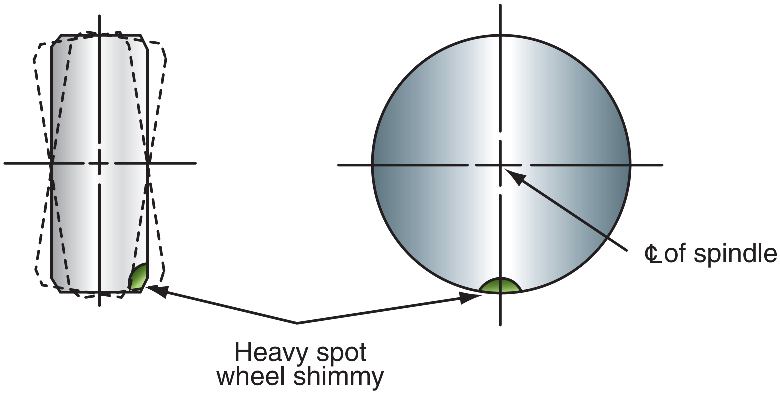

FIGURE 45-33 Dynamic wheel balancing calls for a weight to be attached to the wheel to compensate for a heavy spot on the wheel.

inside of the wheel and one on the outside, at the point of unbalance. This corrects the couple action or wiggle of the wheel assembly. Also, note that dynamic balance is obtained, while static balance remains unaffected.

Wheel Balancing

The most commonly used dynamic wheel balancer requires that the tire/wheel assembly be taken off and mounted on the balancer's spindle. The machine spins the entire assembly and determines the correct placement of weights to correct any static or dynamic imbalance. The results are shown in the balancer's display, which indicates where and how much weight to apply to the wheel. Newer balancers can help hide adhesive weights behind wheel spokes to give the wheel a cleaner appearance. There are several electronic dynamic/static balancer units available that will permit balancing while the wheel and tire are on the car. A switch on the console sets the machine for either static or dynamic balancing or both. When the wheel balancing assembly is mounted for static balancing, it rotates until the heavy spot falls to the bottom. Weights are added to balance the assembly.

In the dynamic balance mode, the wheel assembly is rotated at high speed. Observing the balance scale, the operator reads out the amount of weight that has to be added and the location where the weights should be placed.

Many newer wheel balance machines also check for wheel and tire runout. These machines may use cameras or lasers to monitor wheel and tire movement while spinning the tire and checking the balance.

Road Force Measurements The wheel balancer shown in **Figure 45–34** is designed to also eliminate all causes of vibration due to the wheel and tire assembly. Like many other current wheel balancers, this unit can simulate a road test with a load roller. This roller applies a heavy force on the tire while it is rotating on the balancer. The roller also measures the deflection of the tire as it rolls under pressure. The machine then makes recommendations for the service required to remove all runout and ensure vibration-free operation.

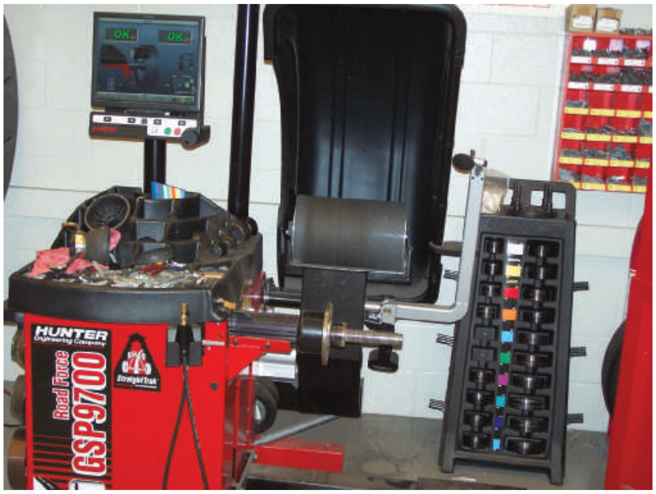

FIGURE 45-34 A computerized "road force" tire balancer.

Wheel Bearings

The purpose of all bearings is to allow a shaft to rotate smoothly in a housing or to allow the housing to rotate smoothly around a shaft. Wheel and axle bearings do this for a vehicle's wheels. Typically, on driving axles, the wheel is mounted to the hub of an axle shaft and the shaft rotates within a housing on an axle bearing. Wheel bearings are used on nondriving axles. The wheel's hub rotates on a shaft called the spindle. Axle bearings are typically serviced with the drive axle. Tapered roller wheel bearings, however, require periodic maintenance and are

often serviced with suspension and brake work. Although there is a distinction between axle and wheel bearings, the bearings for the front wheels on a FWD and 4WD vehicle are commonly called wheel bearings. Regardless of what they are called, bad bearings can cause noise, vibration, handling, and tire wear problems.

Tapered Roller Bearing Troubleshooting

Bearings rarely fail suddenly. Rather, they deteriorate slowly because of dirt, lack of lubrication, and improper adjustment. Bearing wear and failure are almost always accompanied by noise and/or vibration.

Normal bearing sounds should be uniform as the wheel spins on its spindle. An uneven rumble or a grinding sound indicates possible bearing problems. While rotating the wheel, try to move it in and out on the spindle and note the amount of movement. Worn or damaged bearings or bearings that need adjustment will have a noticeable amount of end play. Also grasp the top and bottom of the tire and try to wobble the wheel and tire back and forth. You should feel little or no wobble.

End play can be measured with a dial indicator placed against the wheel hub. Set the indicator to zero, move the wheel in and out on the spindle, and note the reading. Compare your readings to specifications.

Inspect the wheel and the brake drum or rotor for grease that may be leaking past a bad seal. Bearing grease can contaminate brake linings, and a leaking grease seal can let dirt into the bearing. A leaking seal must be replaced, but the bearings also must be cleaned, inspected, and repacked to be sure they have not been damaged. Whether you are installing a used bearing or installing a new one, always install a new grease seal and cotter pin.

Front Wheel Tapered Roller Bearing Service

Most front wheel bearings are sealed units and are lubricated for life. They should be replaced and serviced as an assembly. On older cars and trucks, the nondriven front or rear wheel hub bearing assembly has two tapered bearings **(Figure 45–35)** facing each other. Each of the bearings rides in its own race. These bearings are serviceable and require periodic lubrication and adjustment. Put on a pair of nitrile gloves before servicing the bearings. It will save you a lot of time cleaning yourself up if you do. The following are general procedures for servicing tapered roller bearings.

1. Using a special dust cap removal tool **(Figure 45–36)**, wiggle the cap out of its recess in the hub.
2. Now remove the cotter pin and locknut from the end of the spindle.
3. Loosen the spindle nut while supporting the brake assembly and hub. On many vehicles the

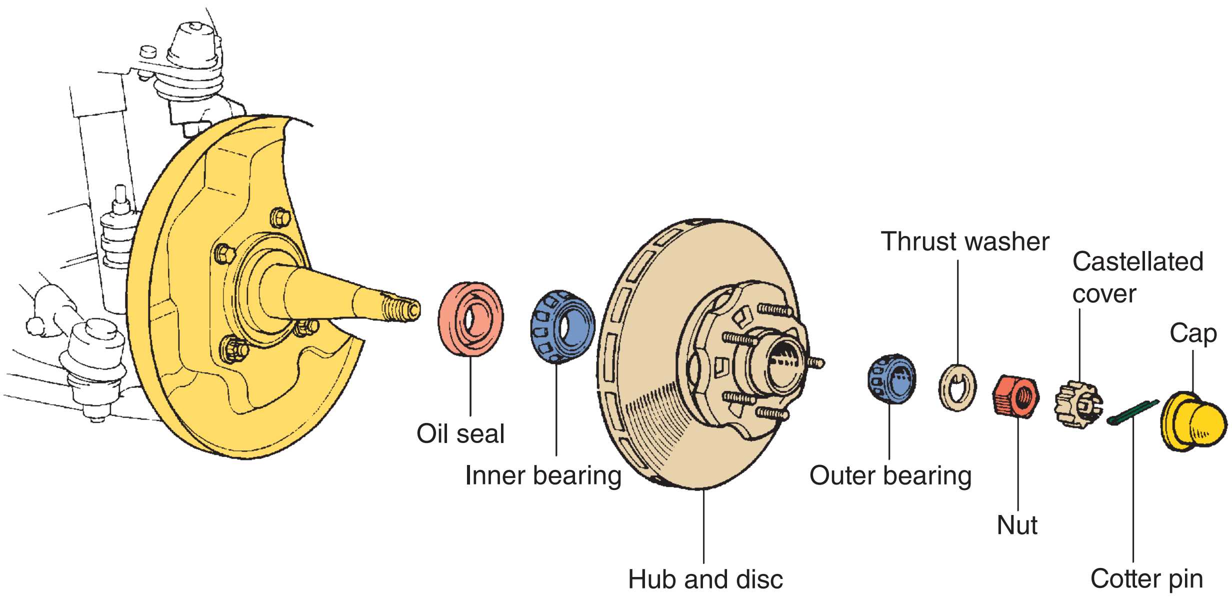

FIGURE 45–35 An exploded view of a typical front wheel bearing assembly for a RWD vehicle.

FIGURE 45-36 A special tool for removing a dust cap.

brake caliper must be removed to remove the brake disc and hub.

4. Once the hub is free from the spindle, remove the spindle nut and the washer behind the nut. Move the hub slightly forward, and then push it back. This should free the outer bearing so you can remove the hub assembly.

A grease seal located on the back of the hub normally keeps the inner bearing from falling out when the hub is removed. To remove the bearing assembly, the grease must be removed. In most cases, the seal can be pried out of the hub. The inner bearing should then fall out. Keep the outer bearing and inner bearing separated if you plan on reusing them.

5. Wipe the grease off the bearings and races and use a parts cleaner to clean them **(Figure 45–37)**. While doing this, pay close attention to the condition and movement of the bearings. The bearings need to rotate smoothly. Also visually inspect the bearings and races; any noticeable damage means they should be replaced. Also inspect the spindle. If it is damaged or excessively worn, the steering knuckle assembly should be replaced.

FIGURE 45-37 Thoroughly clean the bearings and races and then carefully inspect them before reusing them.

Whenever a bearing is replaced, its race must be replaced with it. Races are pressed in and out of the hub. Typically, the old race can be driven out with a large drift punch and a hammer. Once the race has been removed, wipe all grease from the inside of the hub. The new race should be installed with the proper soft-faced driver.

6. During assembly, the bearings and hub assembly must be thoroughly lubricated **(Figure 45–38)**. Care must be taken not to get grease on the brake disc or on any part that will directly contact the disc. Always use the recommended grease. The grease must be able to withstand much heat and friction. If the wrong grease is used, it may not offer the correct protection or it may liquefy from the heat and leak out of the seals.

7. The bearings must be packed with new grease. It is important that the grease be forced into and around all of the rollers in the bearing. Merely coating the outside of the bearing with grease will not do the job. A bearing packer does the best job at packing in the grease.
8. Install the greased inner bearing into the hub and install a new grease seal into the hub. To avoid damaging the seal, use the correct size driver to press the seal into the hub.
9. Lubricate the spindle, and then slip the hub over the spindle.
10. Install the outer bearing, washer, and locknut.

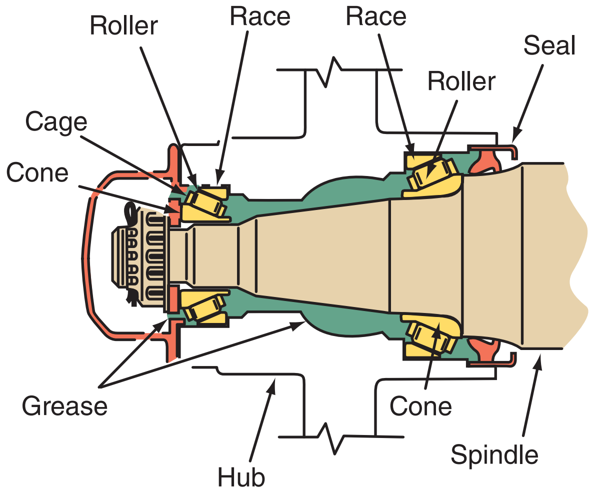

FIGURE 45-38 Wheel bearing lubrication.

Warning! Throughout this entire process, your hands will have grease on them. Be very careful not to touch the brake assembly with your greasy hands. Clean them before handling the brake parts or use a clean rag to hold the brake assembly.

Wheel Bearing Adjustment The locknut should be adjusted to the exact specifications given by the manufacturer. Often it is tightened and loosened before it is adjusted. The initial tightening seats the bearings into their races.

Hub and Bearing Assemblies

The front bearing arrangement used on most vehicles is often nonserviceable. To replace these bearings, either the hub unit is unbolted and removed or the bearing must be pressed in and out of the hub.

To replace a bolted-in hub, you have to remove the bolts securing the assembly to the steering knuckle **(Figure 45–39)**. To get access to these bolts, you may need to remove axle shaft or push it back out of the hub a bit to access the bolts. Depending on the vehicle, you may have to separate the knuckle from the lower ball joint or strut to get enough room to remove the hub retaining bolts. Remove the brake caliper, bracket and rotor and remove the hub assembly. The hubs can be difficult to remove if rusted or corroded in place. Once the bearing is out, clean the surface of the knuckle and the bore where the bearing attaches to ease installation. Install the new assembly and torque the bolts to specifications. When tightening the axle nut, do not use an impact to seat the nut. Hand tighten the nut and then torque to specifications. Overtightening the axle nut can damage the new bearing and lead to rapid wear and failure.

PROCEDURE

To properly adjust front tapered bearings, follow these steps:

STEP 1 Support the rotor or drum with one hand and install the outer bearing and thrust washer into the hub.

STEP 2 Finger tighten the bearing adjusting nut against the thrust washer.

STEP 3 Then adjust the bearings by one of the following methods:

a. Rotate the drum or rotor and snug up the adjusting nut with a wrench to seat the bearings. While continuing to rotate the drum or rotor, back off the nut ¼ to ½ turn or until it is barely loose. Then tighten the nut by hand to a snug fit.

b. Rotate the drum or rotor and tighten the adjusting nut with a torque wrench to the specified torque. Then back off the nut $^{1}/_{3}$ turn and retorque it to the specified value while continuing to rotate the drum or rotor. Final torque is usually in inch-pounds.

c. Rotate the drum or rotor and tighten the adjusting nut with a torque wrench to 12 to 25 foot-pounds. Then back off the nut ¼ to ½ turn or until it is just loose. Mount the base of a dial indicator as close as possible to the center of the hub. Locate the tip of the indicator's plunger on the tip of the spindle. Set the indicator to zero. Move the drum or rotor in and out and note the indicator reading. Turn the adjusting nut as necessary to obtain the specified end play, which is usually 0.001 to 0.005 inch (0.025 to 0.125 mm).

STEP 4 After adjustment, install the locknut over the top of the adjusting nut so the slots in the locknut align with the cotter pin hole in the spindle.

STEP 5 Install a new cotter pin through the spindle and locknut and bend its ends to secure it. Reinstall the dust cap in the hub.

STEP 6 If the axle has drum brakes that were backed off to allow removal of the drum, readjust the brakes.

STEP 7 If the axle has disc brakes, reinstall the caliper.

STEP 8 Reinstall the wheel and tire and lower the vehicle to the ground.

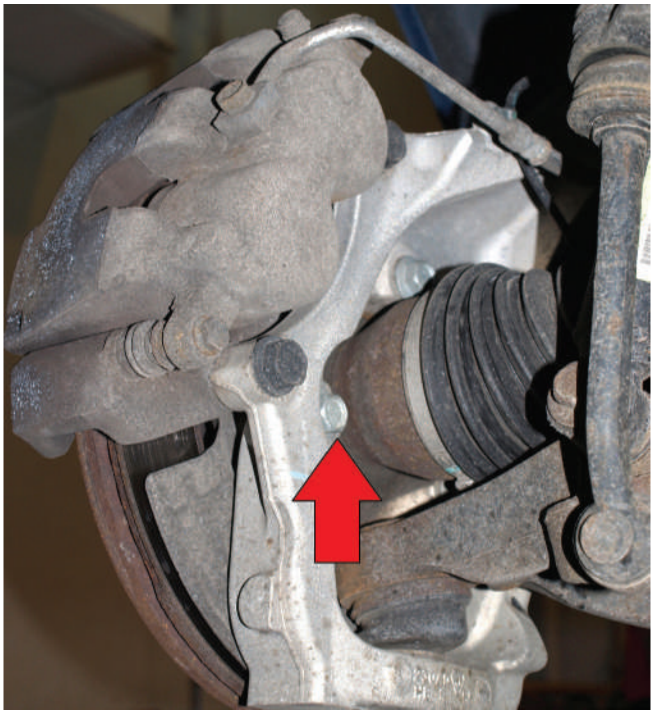

FIGURE 45-39 The bolts holding the wheel bearing to the knuckle.

To replace a pressed-in bearing, the axle or half shaft is removed, as is the steering knuckle and hub assembly. First, press the hub flange from the bearing. A hydraulic press or a bearing tool **(Figure 45–40)** is used to press both the hub flange and bearing from and back into the knuckle. When installing the new bearing, note the installation instructions as some bearings are directional or need to be installed one way so the ABS wheel speed sensor can function properly. This means the bearings is meant to rotate mainly in one direction or it may have two different sized inner races. The bearings may be sealed

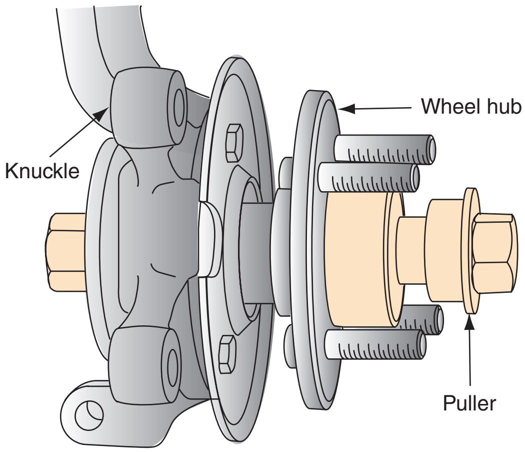

FIGURE 45-40 Pressing the hub flange back into the bearing.

SHOP TALK

Because an axle nut is heavily torqued, it is wise to loosen the nut before the vehicle is raised for service. The weight of the vehicle on the tires will stop the hub from rotating while the nut is being loosened. The same holds true for final torquing. Tighten the nut as tight as possible with the vehicle raised, then lower the vehicle and torque the nut to specifications.

and require no additional lubrication or they may need to be packed with grease when they are reassembled. In most cases, the bearings are not adjusted. A heavily torqued axle nut is used to hold the assembly in place on the axle. This nut is typically replaced after it has been removed and is staked in place after it is tightened.

Rear Hubs

The rear bearings on a FWD vehicle are serviced in the same way as the nondriving front wheel bearings. Most RWD axle bearings are of the straight roller bearing design, in which the drive axle tube serves as the bearing race. Some rear wheel axle bearings are of the ball or tapered roller bearing type.

Wheel Bearing Grease Specification

The grease for wheel bearings should be smooth textured, consist of soaps and oils, and be free of filler and abrasives. Recommended are lithium complex (or equivalent) soaps, or solvent-refined petroleum oils. Additives could be added to inhibit corrosion and oxidation. The grease should be noncorrosive to bearing materials with no chance of separating during storage or use.

Using the correct amount of lube is also essential. Failure to maintain proper lubrication might result in bearing damage, causing a wheel to lock. Greases are classified by the National Lubricating Grease Institute (NLGI) to indicate their application.

SUMMARY

- Wheels are made of either stamped or pressed steel discs riveted or welded into a circular shape or are die-cast or forged aluminum or magnesium rims.
- The primary purpose of tires is to provide traction. They are also designed to carry the weight of the vehicle, to withstand side thrust over varying speeds and conditions, to transfer braking and driving torque to the road, and to absorb much of the rock shock from surface irregularities.
- Pneumatic tires are of two types: those that use inner tubes and those that do not. The latter are called tubeless tires and are the only type used on passenger cars today.
- There are three types of tire construction on the road today: bias ply, belted bias ply, and radial ply.
- Tires are rated by their profile, ratio, size, and load range.
- An ideal tire is one that wears little, holds the road well to provide sure handling and braking, and provides a cushion from road shock. It should also provide maximum grip on dry roads, wet roads, and snow and ice, and operate quietly at any speed.
- The number and size of the blocks, sipes, and grooves on a tire's tread determines how much rubber contacts the road, how much water can be displaced, and how quiet the tire will be during travel.
- To maximize tire performance, inspect for signs of improper inflation and uneven wear, which can indicate a need for balancing, rotation, or alignment. Tires should also be checked frequently for cuts, bruises, abrasions, and blisters, and for stones or other objects that might have become imbedded in the tread.
- A properly inflated tire gives the best tire life, riding comfort, handling stability, and even gas mileage during normal driving conditions.
- To equalize tire wear, most car and tire manufacturers recommend that the tires be rotated. It must be remembered that front and rear tires perform different jobs and can wear differently, depending on driving habits and the type of vehicle.
- Most tires used today have built-in tread wear indicators to show when tires need replacement.

- There are three popular methods of tire repair: head-type plug, cold patch repair, and hot patch repair.
- There are two types of wheel balancing: static balance and dynamic balance.
- The bearings on an axle that drives the wheels are called axle bearings. Wheel bearings are used on nondriving axles. Axle bearings are typically serviced with the drive axle. Wheel bearings require periodic maintenance and are often serviced with suspension and brake work.
- Bad axle and wheel bearings will cause handling and tire wear problems.
- The front wheel hubs on ball or tapered roller bearings are lubricated by wheel bearing grease.
- Rear wheels are bolted to integral or detachable hubs.

Like the other systems on cars and light trucks, the suspension system has become more advanced through the years. These advances have been made to provide better and safer handling and a better ride. Today, front and rear suspensions have many parts and can be quite complex.

As a vehicle moves, the suspension and tires must react to the current driving conditions. Specifically, the suspension system:

- Supports the weight of the vehicle
- Keeps the tires in contact with the road
- Controls the direction of the vehicle's travel
- Attempts to maintain the correct vehicle ride height
- Maintains proper wheel alignment
- Reduces the effect of shock forces as the vehicle travels on an irregular surface

Frames

To provide a rigid structural foundation for the vehicle body and a solid anchorage for the suspension system, a frame of some type is essential. There are two basic frames in common use today.

Conventional Frame Construction

In the conventional body-over-frame construction, the frame is the vehicle's foundation. The body and all major parts of a vehicle are attached to the frame **(Figure 46–1)**. It must provide the support and strength needed by the assemblies and parts attached to it. In other words, the frame is an independent, separate component because it is not welded to any of the major units of the body shell.

Unibody Construction

Unibody construction has no separate frame. The body is constructed in such a manner that the body parts themselves supply the rigidity and strength required to maintain the structural integrity of the car **(Figure 46–2)**. The unibody design significantly lowers the base weight of the car, and that, in turn, increases gas mileage capabilities.

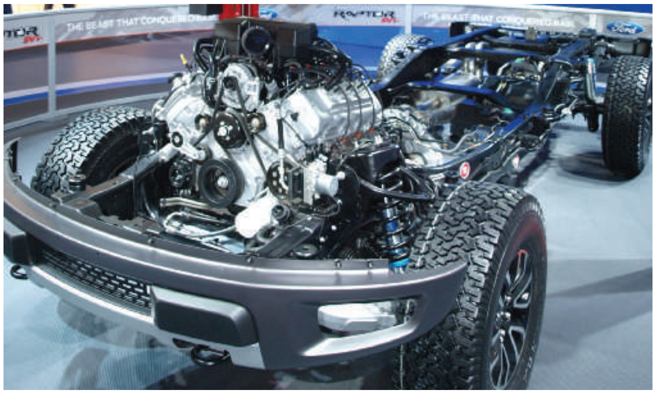

FIGURE 46–1 An example of body-over-frame construction.

FIGURE 46–2 Unibody construction is the most common frame design today.

Suspension System Components

Nearly all automotive suspensions have the same basic components and they operate similarly. The basic differences between the suspensions found on various vehicles are the construction and placement of the parts.

Springs

A spring is the core of all suspension systems. Springs carry the weight of the vehicle and absorb shock forces while maintaining correct riding height. They are compressible links between the vehicle's frame and body and the tires. Doing this, they dampen road shock and provide a comfortable ride. If a spring is worn or damaged, other suspension parts will shift out of their proper positions and will experience increased wear.

Various types of springs are used in suspension systems **(Figure 46–3)** —coil, torsion bar, leaf (both mono- and multileaf types), and air springs. Springs are mounted in rubber or nylon to reduce road shock and noise.

Automotive springs are generally classified by the amount they compress under a specific load. This is referred to as the spring rate. A force (weight) applied to a spring causes it to compress in direct proportion to the force applied. When that force is

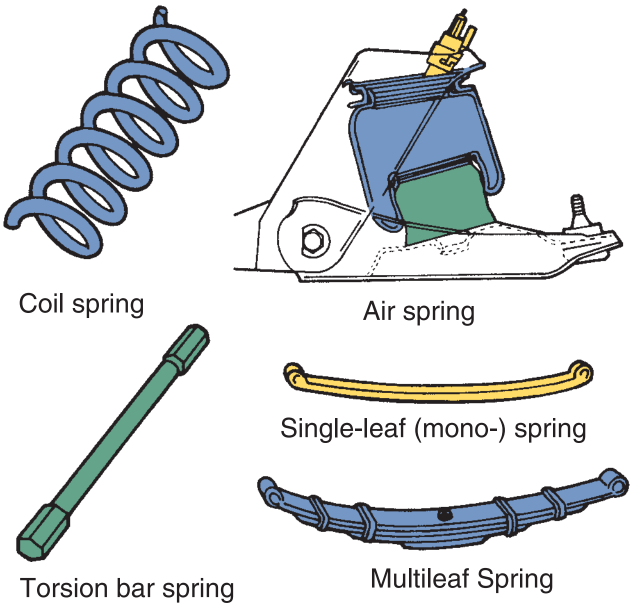

FIGURE 46–3 Various types of automotive springs.

removed, the spring returns to its original position if it is not overloaded. This is why a heavy vehicle needs stiffer springs than a lightweight car.

The springs take care of two fundamental vertical actions: jounce and rebound. **Jounce**, or compression, occurs when a wheel hits a bump and moves up **(Figure 46–4A)**. When this happens, the suspension system acts to pull in the top of the wheel, maintaining an equal distance between the two wheels and preventing a sideways scrubbing action as the wheel moves up and down. **Rebound**, or extension, occurs when the wheel hits a dip or hole and moves downward **(Figure 46–4B)**. In this case, the suspension system acts to move the wheel in at both the top and bottom equally, while maintaining an equal distance between the wheels.

When the spring experiences compression or extension, it stores energy. This energy forces the spring to return to its normal shape. The spring oscillates between jounce and rebound until all energy has moved from the spring. Each oscillation becomes smaller until it stops. A **shock absorber** is added to each suspension to dampen and stop the motion of the spring after jounce.

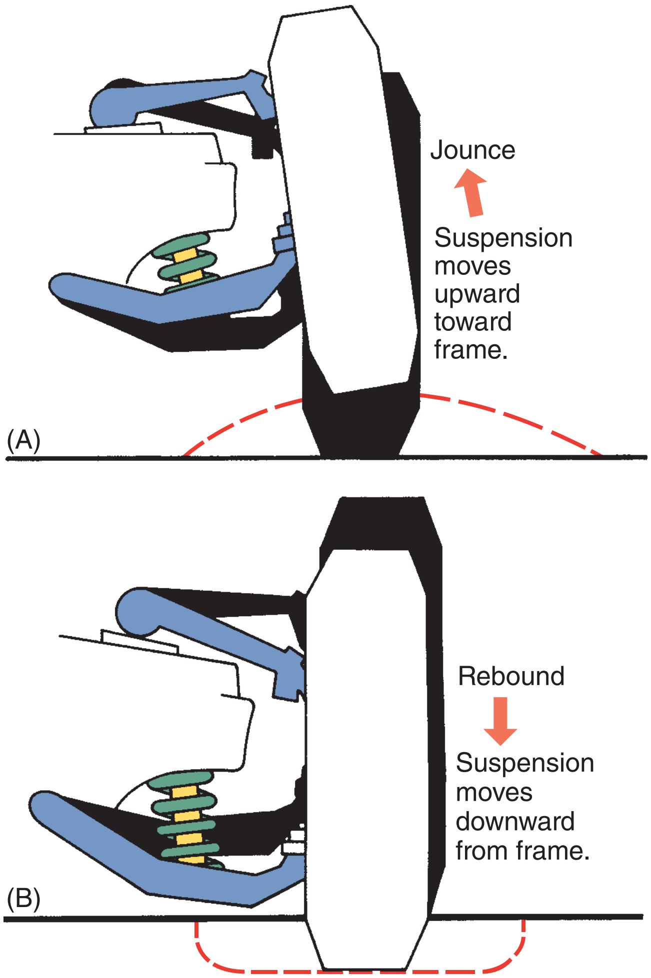

FIGURE 46–4 (A) Upward and (B) downward suspension movement.

FIGURE 46–5 The different designs of coil springs.

Coil Springs Two basic designs of coil springs are used: linear rate and variable rate **(Figure 46–5)**. **Linear rate** springs characteristically have one basic shape and a consistent wire diameter. All linear springs are wound from a steel rod into a cylindrical shape with even spacing between the coils. As the load is increased, the spring is compressed and the coils twist (deflect). As the load is removed, the coils flex (unwind) back to the normal position. The amount of load necessary to deflect the spring 1 inch (25.4 mm) is the spring rate. On linear rate springs this is a constant rate, no matter how much the spring is compressed. For example, 250 pounds (112 kg) compress the spring 1 inch (25.4 mm) and 750 pounds (340 kg) compress the spring 3 inches (76.2 mm). Spring rates for linear rate springs are normally calculated between 20 percent and 60 percent of the total spring deflection.

Variable rate spring designs are characterized by a combination of wire sizes and shapes. The most commonly used variable rate springs have a consistent wire diameter, are wound in a cylindrical shape, and have unequally spaced coils. This type of spring is called a progressive rate coil spring.

The design of the coil spacing gives the spring three functional ranges of coils: inactive, transitional, and active. Inactive coils are usually the end coils and introduce force into the spring. Transitional coils become inactive as they are compressed to their point of maximum load-bearing capacity. Active coils work throughout the entire range of spring loading. Theoretically in this type of design, at stationary loads the inactive coils are supporting all of the vehicle's weight. As the loads are increased, the transitional coils take over until they reach maximum capacity. Finally, the active coils carry the remaining

overload. This allows for automatic load adjustment while maintaining vehicle height.

Another common variable rate design uses tapered wire to achieve this same type of progressive rate action. In this design, the active coils have a large wire diameter and the inactive coils have a small wire diameter.

Later designs of variable rate springs deviate from the old cylindrical shape. These include the truncated cone, the double cone, and the barrel spring. The major advantage of these designs is the ability of the coils to nest, or bottom out, within each other without touching, which lessens the amount of space needed to store the springs in the vehicle.

Unlike a linear rate spring, a variable rate spring has no predictable standard spring rate. Instead, it has an average spring rate based on the load of a predetermined spring deflection. This makes it impossible to compare a linear rate spring to a variable rate spring. Variable rate springs, however, handle a load of up to 30 percent over standard rate springs in some applications.

Leaf Springs Although leaf springs were the first type of suspension spring used on automobiles, today they are generally found only on light-duty trucks, vans, and some passenger cars. There are three basic types of leaf springs: multiple leaf, monoleaf, and fiber composite.

Multiple-Leaf Springs. Multiple-leaf springs consist of a series of flat steel leaves that are bundled together and held with clips or by a bolt placed slightly ahead of the center of the bundle. One leaf, called the main leaf, runs the entire length of the spring. The next leaf is a little shorter and attaches to the main leaf. The next leaf is shorter yet and attaches to the second leaf, and so on. This system allows almost any number of leaves to be used to support the vehicle's weight **(Figure 46–6)**. It also

FIGURE 46–6 An example of stacked, multiple-leaf springs used on a light-duty pickup truck.

gives a progressively stiffer spring. The spring easily flexes over small distances for minor bumps. The farther the spring is deflected, the stiffer it gets. The more leaves and the thicker and shorter the leaves, the stronger the spring. It must be remembered that as the spring flexes, the ends of the leaves slide over one another. This sliding could be a source of noise and can also produce friction. These problems are reduced by interleaves of zinc and plastic placed between the spring's leaves. As the multiple leaves slide, friction produces a harsh ride as the spring flexes. This friction also dampens the spring motion.

Multiple-leaf springs have a curve in them. This curve, if doubled, forms an ellipse. Thus, leaf springs are sometimes called semielliptical or quarter-elliptical. The semi or quarter refers to how much of the ellipse the spring actually describes. The vast majority of leaf springs are semielliptical.

Leaf springs are typically mounted at right angles to the axle **(Figure 46–7)**. However, on late-model Toyota trucks, the leaf springs are angled outward toward the front, so the distance between the front ends of the two springs is greater than the distance

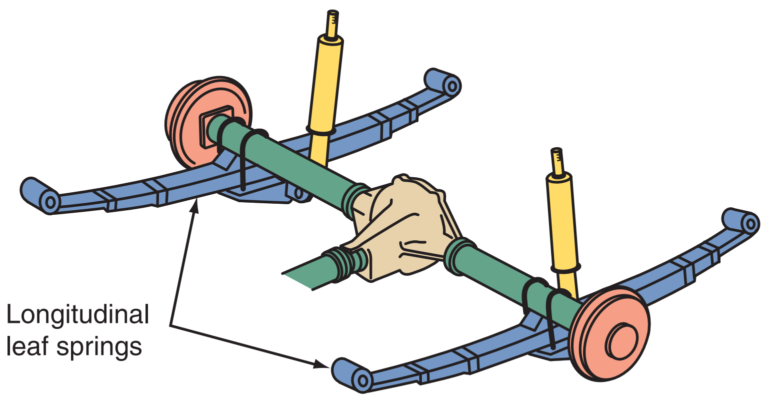

FIGURE 46–7 These leaf springs support and locate the drive axle.

between the rears of the springs. In addition to absorbing road shock, leaf springs also serve as a mount for the drive axle. A centering pin is often used to keep the axle properly located on the springs. If a spring is broken or not in its proper position, the drive axle may be sitting at an angle; this will cause handling problems.

Some vehicles have a transversely mounted leaf spring. The center of the spring is mounted to the vehicle's chassis and the outer ends are fastened to the ends of the axle housing or wheel spindles.

The front eye of the main leaf at either end of the axle is attached to a bracket on the frame of the vehicle with a bolt and bushing connection. The rear eye of the main leaf is secured to the frame with a shackle, which permits some fore and aft movement **(Figure 46–8)** in response to physical forces of acceleration, deceleration, and braking.

Monoleaf Springs. Monoleaf or single-leaf springs are usually the tapered plate type with a heavy or thick center section tapering off at both ends. This provides a variable spring rate for a smooth ride and good load-carrying ability. In addition, single-leaf springs do not have the noise and static friction characteristic of multiple-leaf springs.

Fiber Composite Springs. While most leaf springs are still made of steel, fiber composite types are increasing in popularity **(Figure 46–9)**. Some automotive people call them plastic springs in spite of the fact that the springs contain no plastic at all. They are made of fiberglass, laminated and bonded together by tough polyester resins. The long strands of fiberglass are saturated with resin and bundled together by wrapping (a process called filament winding) or squeezed together under pressure (compression molding).

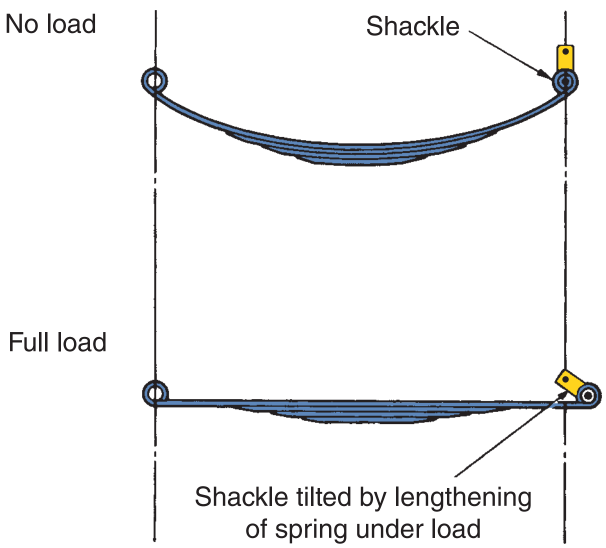

FIGURE 46–8 The action of a leaf spring as it compresses.

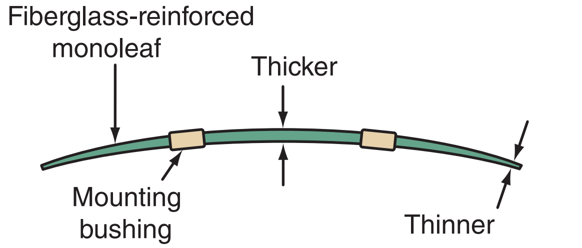

FIGURE 46–9 The construction of a fiberglass-reinforced monoleaf spring.

Fiber composite leaf springs are incredibly lightweight and possess some unique ride control characteristics. Conventional monoleaf steel springs are real heavyweights, tipping the scale at anywhere from 25 to 45 pounds (11 to 20 kg) apiece. Some multiple-leaf springs can weigh almost twice as much. A fiber composite leaf spring is a featherweight by comparison, weighing a mere 8 to 10 pounds (3.6 to 4.5 kg). As every performance enthusiast knows, springs are dead weight. Reducing the weight of the suspension not only reduces the overall weight of the vehicle, but also reduces the sprung mass of the suspension itself. This reduces the spring effort and amount of shock control that is required to keep the wheels in contact with the road. The result is a smoother riding, better handling, and faster responding suspension, which is exactly the sort of thing every performance enthusiast wants.

Air Springs Another type of spring, an air spring, is used in an air-operated microprocessor-controlled system that replaces the conventional coil springs with air springs to provide a comfortable ride and automatic front and rear load-leveling. This system, fully described later in this chapter, uses four air springs to carry the vehicle's weight. The air springs are located in the same positions where coil springs are usually found. Each spring consists of a reinforced rubber bag pressurized with air. The bottom of each air bag is attached to an inverted pistonlike mount that reduces the interior volume of the air bag during jounce **(Figure 46–10)**. This has the effect of increasing air pressure inside the spring as it is compressed, making it progressively stiffer. A vehicle equipped with an electronic air suspension system is able to provide a comfortable street ride, about a third softer than conventional coil springs. At the same time, its variable spring rate helps absorb bumps and protect against bottoming.

FIGURE 46-10 A rear-suspension setup with air springs.

Torsion Bar Suspension System

Torsion bars serve the same function as coil springs. In fact, they are often described as straightened-out coil springs. Instead of compressing like coil springs, a torsion bar twists and straightens out on the recoil. That is, as the bar twists, it resists up-and-down movement. One end of the bar—made of heat-treated alloy spring steel—is attached to the vehicle frame. The other end is attached to the lower control arm **(Figure 46–11)**. When the wheel moves up and down, the lower control arm is raised and lowered. This twists the torsion bar, which causes it to absorb

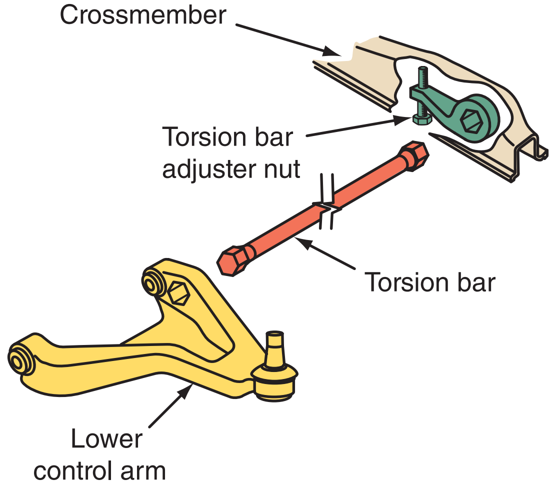

FIGURE 46-11 A torsion bar setup.

road shocks. The bar's natural resistance to twisting quickly restores it to its original position, returning the wheel to the road.

When torsion bars are manufactured, they are prestressed to give them fatigue strength. Because of directional prestressing, torsion bars are directional. The torsion bar is marked either right or left to identify on which side it is to be used.

Because the torsion bar is connected to the lower control arm, the lower ball joint is the load carrier. A shock absorber is connected between the lower control arm and the frame to damp the twisting motion of the torsion bar.

Many late-model pickups and SUVs use torsion bars in their front suspensions. They are primarily used in this type vehicle because they can be mounted low and out of the way of the driveline components.

Shock Absorbers

Shock absorbers damp or control motion in a vehicle. If unrestrained, springs continue expanding and contracting after a blow until all the energy is absorbed. Not only would this lead to a rough and unstable—perhaps uncontrollable—ride after consecutive shocks, it would also create a great deal of wear on the suspension and steering systems. Shock absorbers prevent this. Despite their name, they actually dampen spring movement instead of absorbing shock. As a matter of fact, in England and almost everywhere else but the United States, shock absorbers are referred to as **dampers**.

Today's conventional shock absorber is a velocity-sensitive hydraulic damping device. The faster it moves, the more resistance it has to the movement **(Figure 46–12)**. This allows it to automatically adjust to road conditions. A shock absorber works on the principle of fluid displacement on both its compression (jounce) and extension (rebound) cycles. A typical car shock has more resistance during its extension cycle than its compression cycle. The extension cycle controls motions of the vehicle body spring weight. The compression cycle controls the same motions of the unsprung weight. This motion energy is converted into heat energy and dissipated into the atmosphere.

Shock absorbers can be mounted either vertically or at an angle. Angle mounting of shock absorbers improves vehicle stability and dampens accelerating and braking torque.

Conventional hydraulic shocks are available in two styles: single-tube and double-tube. The vast majority of domestic shocks are double-tubed. While they are

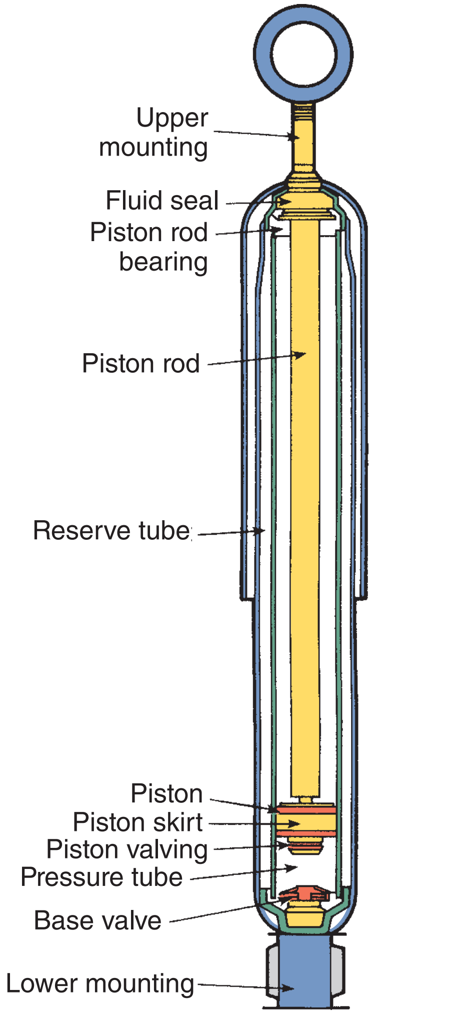

FIGURE 46–12 A cross section of a conventional shock absorber.

a little heavier and run hotter than the single-tubed type, they are easier to make. The double-tube shock has an outer tube that completely covers the inner tube. The area between the tubes is the oil reservoir. A compression valve at the bottom of the inner tube allows oil to flow between the two tubes. The piston moves up and down inside the inner tube.

In a single monoshock, there is a second floating piston near the bottom of the tube. When the fluid volume increases or decreases, the second piston moves up and down, compressing the reservoir. The fluid does not move back and forth between a reservoir and the main chamber. There are no other valves in a single-tube shock besides those in the main piston. The second piston prevents the oil from splashing around too much and getting air bubbles in it. Air in the shock oil is detrimental. Air, unlike oil, is compressible and slips past the piston easily. When this happens, the result is a shock that offers poor vehicle control on bumpy roads.

In addition to these conventional hydraulic shocks, there are a number of others the technician may encounter.

Gas-Charged Shock Absorbers On rough roads, the passage of fluid from chamber to chamber becomes so rapid that foaming can occur. Foaming is simply the mixing of the fluid with any available air. Since aeration can cause a skip in the shock's action, engineers have sought methods of eliminating it. One is the spiral groove reservoir, the shape of which breaks up bubbles. Another is a gas-filled cell or bag (usually nitrogen) that seals air out of the reservoir so the shock fluid can only contact the gas.

A gas-charged shock absorber **(Figure 46–13)** operates on the same hydraulic fluid principle as

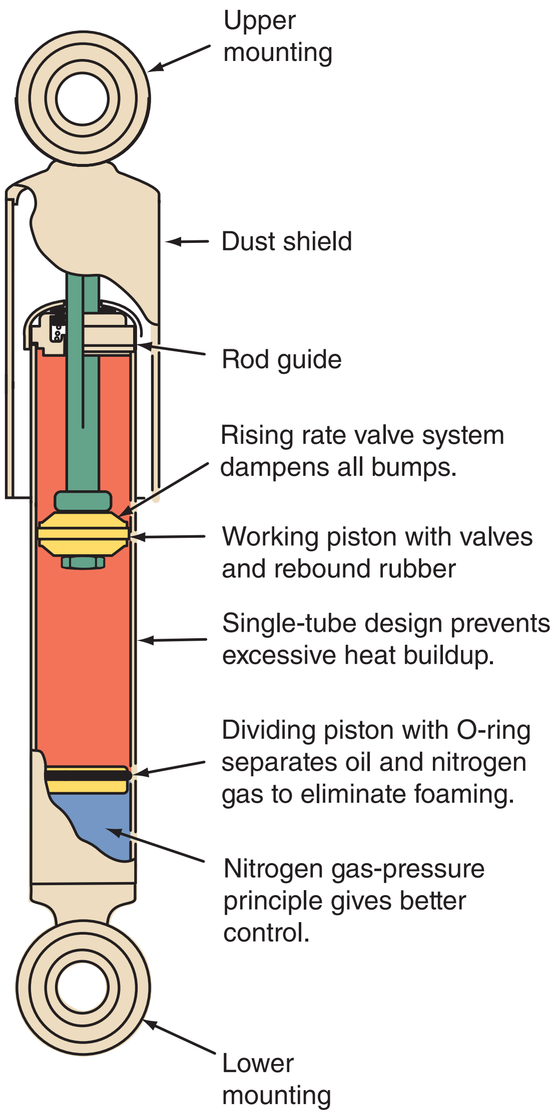

FIGURE 46–13 Gas-pressure damped shocks operate like conventional oil-filled shocks. Gas is used to keep oil pressurized, which reduces oil foaming and increases efficiency under seven conditions.

conventional shocks. It uses a piston and oil chamber similar to other shock absorbers. Instead of a double-tube with a reserve chamber, it has a dividing piston that separates the oil chamber from the gas chamber. The oil chamber contains a special hydraulic oil, and the gas chamber contains nitrogen gas under pressure equal to approximately 25 times atmospheric pressure.

As the piston rod moves downward in the shock absorber, oil is displaced, just as it is in a double-tube shock. This oil displacement causes the divided piston to press on the gas chamber. The gas is compressed and the chamber reduces in size. When the piston rod returns, the gas pressure returns the dividing piston to its starting piston. Whenever the static pressure of the oil column is held at approximately 100 to 360 psi (690 to 2.482 kPa) (depending on the design), the pressure decreases behind the piston and so cannot be high enough for the gas to escape from the oil column. As a result, a gas-filled shock absorber operates without aeration.

Air Shock Systems There are two basic adjustable air shock systems: manual fill and automatic load-leveling. The manual fill system can be installed on almost any vehicle manufactured without it.

There are several different types of manual fill air shock systems available. One common manual fill air shock system uses a high-speed, direct current (DC) motor to transfer a command signal that is manually selected from the driver's seat. In another manual air system, the units are inflated through air valves mounted at the rear of the vehicle. Air lines run between the shocks and the valve. A tire air pressure pump is used to fill the shocks to bring the rear of the vehicle to the desired height.

SHOP TALK

Some high-pressure gas-charged shocks are monotube shocks with fluid and gas in separate chambers. The gas is charged to 360 psi (2.482 kPa). Its basic design does not allow the valving range needed for a more responsive ride over a broad range of road conditions. The high-pressure gas charge can provide a harsh ride under normal driving conditions and is usually found on small trucks.

Dynamic Suspensions Spool Valve Dampers

A new type of shock that is being used in some high-performance applications is the spool valve damper. Instead of using traditional disc-type valves to control oil flow, DSSV dampers use two spool valves, one for compression and one for extension **(Figure 46–14)**. Precisely machined orifices in the spool valves regulate oil flow than conventional shock valves as the outer sliding sleeve moves past the spool valves.

Shock Absorber Ratio Most shock absorbers are valved to offer roughly equal resistance to suspension movement upward (jounce) and downward (rebound). The proportion of a shock absorber's ability to resist these movements is indicated by a numerical formula. The first number indicates jounce resistance. The second indicates rebound resistance. For example, passenger cars with normal suspension requirements use shock absorbers valued at 50/50 (50 percent jounce/50 percent rebound). Damping rates within the shock absorbers are controlled by the size of the piston, the size of the orifices, and the closing force of the valves.

It is important to keep in mind that the shock absorber ratio only describes what percentage of the shock absorber's total control is compression and what percentage is extension. Two shocks with the same ratio can differ greatly in their control capacity. This is one reason the technician must be sure correct replacement shocks are installed on the vehicle.

Stabilizer Bars

Nearly all suspension systems have a **sway bar**, which is also known as the **antisway bar** or stabilizer. This bar, like the shock absorbers, provides

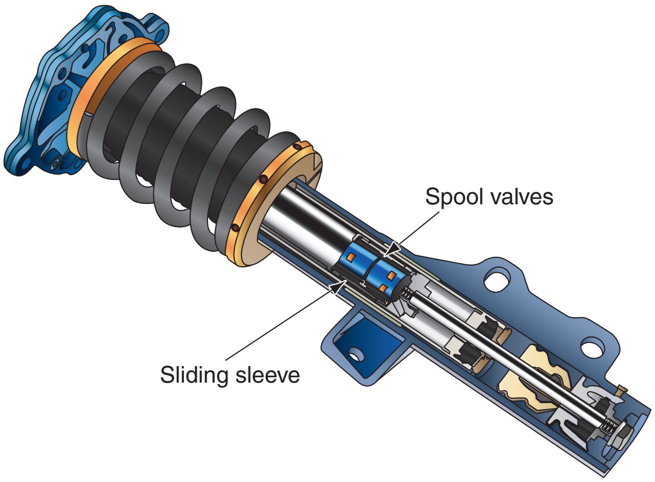

FIGURE 46–14 A spool valve damper.

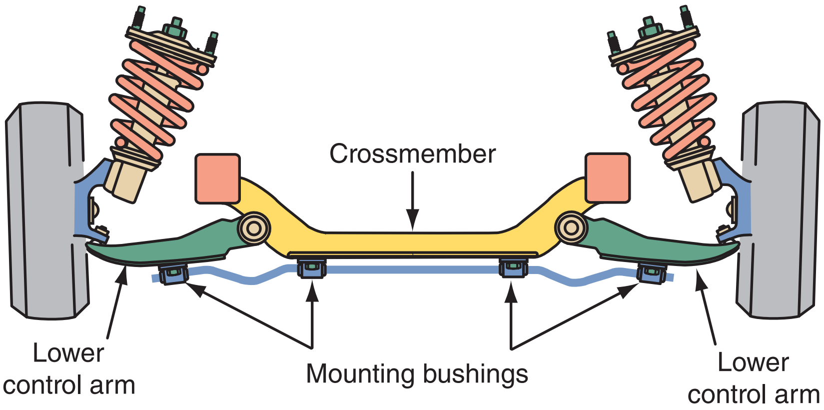

FIGURE 46–15 The typical location of a stabilizer bar.

directional stability by reducing body roll. It is a metal rod running between the opposite lower or upper control arms **(Figure 46–15)**. As the suspension at one wheel responds to the road surface, the sway bar transfers a similar movement to the suspension at the other wheel. For example, if the right wheel is drawn down by a dip in the road surface, the sway bar is drawn with it, creating a downward draw on the left wheel as well. In this way, a more level ride is produced. Sway or lean during cornering is also reduced. Depending on its thickness, the antisway bar can reduce vehicle roll or sway by up to 15 percent.

If both wheels go into a jounce, the sway bar simply rotates in its bushings. When only one wheel goes into jounce, the bar twists like a torsion bar to lift the frame and the opposite side of the suspension. This reduces body roll.

The sway bar is typically a one-piece, U-shaped rod connected to the control arms with rubber bushings, or it can be attached to each control arm by a separate sway bar link **(Figure 46–16)**. The sway bar link may be comprised of a bolt, nut, washers, and rubber bushings. Many modern sway bar links use a steel or plastic rod and ball-socket joints to connect the sway bar to the control arm or strut assembly. The sway bar is also mounted to the frame in the center with rubber bushings. If it is too large, the sway bar causes the vehicle to wander. If it is too small, it has little effect on stability.

Some newer cars and trucks have electronic stabilizer bars **(Figure 46–17)**. In car applications, the action of the stabilizer bar is controlled by a module as part of the stability control system. The amount of resistance provided by the bar can be changed based on driving conditions and the mode selected, such as comfort, sport, or sport +. The motor is used to create resistance to body roll by resisting the movements of the stabilizer bar segments. When driving straight down the road, the system can uncouple the stabilizer bar to allow for a smoother ride.

Strut Rods

Strut rods are used on models that do not use lower A-shaped control arms. In some suspensions, the strut rods also form the sway bar. Strut bars are attached to the lower control arm and frame with bushings, allowing the arm-limited forward and backward movement. Strut rods are directly affected by braking forces and road shocks, and their failure can quickly lead to failure of the entire suspension system.

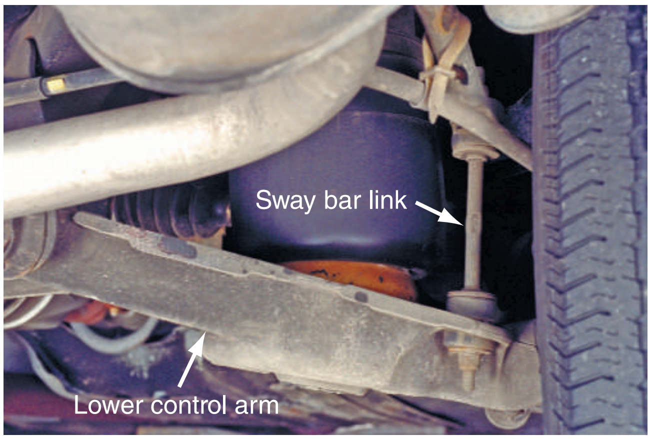

FIGURE 46–16 A sway bar link connects the sway bar to the lower control arm.

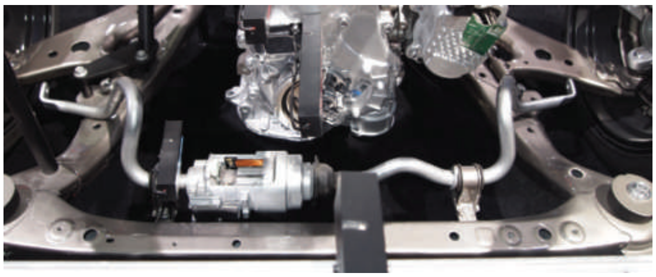

FIGURE 46–17 An electronically controlled or active stabilizer bar.

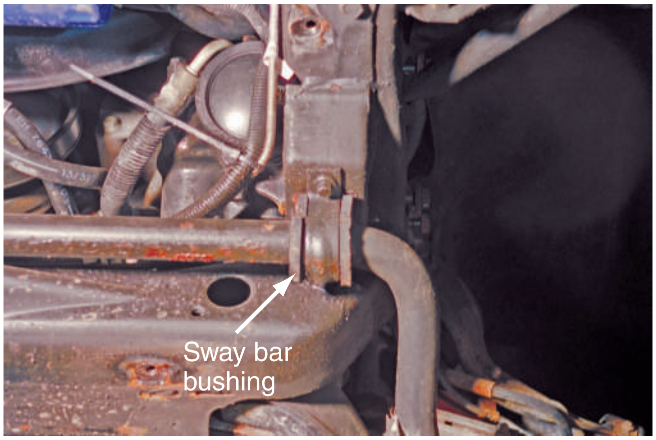

FIGURE 46–18 The center section of a sway bar rides in bushings.

Bushings

Bushings are used at the stabilizer bars **(Figure 46–18)**, control arms, radius arms, and strut rods. They make good suspension system pivots, minimize the number of lubrication points, and allow for slight assembly misalignments. Bushings are able to absorb some of the road shock before the force is transferred to the vehicle's frame, or body.

Suspension bushings are typically made of a rubber material, commonly an elastomer. Elastomers are capable of compressing in response to a force. When the force is removed, elastomers return to their original shape. They also allow movement or shifting of the parts they are between. The amount of movement depends on the design of the bushing. For example, control arms are attached to the frame of the vehicle with rubber elastomeric bushings. The bushings become the pivoting point for the control arms. During suspension travel, the bushings twist as the control arm moves. The bushings, acting like a spring, attempt to untwist and push the control arm back into its original position. This action provides some resistance to suspension movement while the bushings absorb some of the road shock.

This twisting and untwisting of the bushings generate heat. Rough road conditions and/or bad shock absorbers will cause the suspension to move more than normal. This causes more heat to buildup in the bushings, shortening their life. Excessive heat tends to harden the rubber and as the bushings become harder, they break, crack, or fall apart.

Worn suspension bushings may allow suspension parts to change positions **(Figure 46–19)**. This can lead to vibrations, wheel alignment problems, tire wear, and poor ride and handling. Often, a clunking noise when traveling on a rough surface will be an indication of a worn bushing. Worn or damaged bushings should be replaced.

(A)

(B)

FIGURE 46–19 (A) A failing control arm bushing. (B) A completely separated bushing.

Noise may also result from dry bushings and this may be corrected by lubricating them. Only rubber lubricant or a silicone-based lubricant should be used. Rubber bushings should not be lubricated with petroleum-based lubricants. These will cause the bushings to deteriorate.

Performance TIP

Many technicians replace stock rubber bushings with harder bushings made of high-grade polyurethane materials. These bushings do not have the give that rubber bushings do and tend to improve handling, steering response, and ride control. These bushings can also help to reduce torque steer on FWD vehicles.

Independent Front Suspension

Front-suspension systems are fairly complex. They have somewhat contradictory jobs. They must keep the wheels rigidly positioned and at the same time allow them to steer right and left. In addition, because of weight transfer during braking, the front-suspension system absorbs most of the braking torque. While accomplishing this, it must provide good ride and stability characteristics.

MacPherson Strut Suspensions

The **MacPherson strut** suspension is dramatically different in appearance from the traditional independent front suspension **(Figure 46–20)**, but similar components operate in the same way to meet suspension demands. Because of its compact design and being suited to work with FWD configurations, the MacPherson strut is one the most common types of front suspension system being used.

The MacPherson strut suspension's most distinctive feature is the combination of the main elements into a single assembly. It typically includes the spring, upper suspension locator, and shock absorber. It is mounted vertically between the top arm of the steering knuckle and the inner fender panel.

Struts have taken two forms: a concentric coil spring around the strut itself **(Figure 46–21)** and a spring located between the lower control arm and the frame **(Figure 46–22)**. The location of the spring on the lower control arm, not on the strut as in a conventional MacPherson strut system, allows

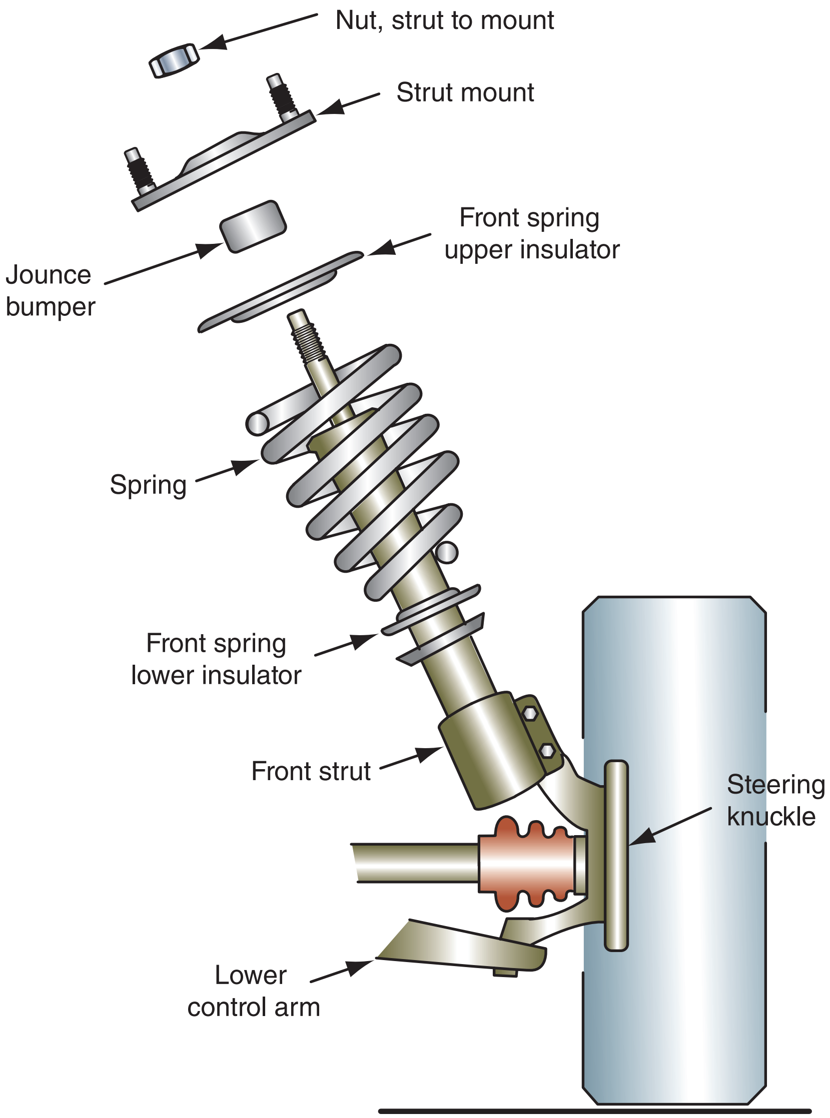

FIGURE 46–20 A complete MacPherson strut front suspension.

FIGURE 46–22 A modified MacPherson suspension has the spring mounted separately from the strut.

minor road vibrations to be absorbed through the chassis rather than be fed back to the driver through the steering system. This system is called modified MacPherson suspension.

Struts

The core element of this type of suspension is the strut. With its cylindrical shape and protruding piston rod, it looks quite similar to the conventional shock absorber. In fact, the strut provides the damping function of the shock absorber, in addition to serving to locate the spring and to fix the position of the suspension.

The shock-damping function is accomplished differently on various types of struts. None of them uses a separate shock absorber as the traditional front suspension does. Some versions are designed so the damper can be independently serviced.

Struts fall into two broad categories: sealed and serviceable units. A sealed strut is designed so the top closure of the strut assembly is permanently sealed. There is no access to the shock absorber cartridge inside the strut housing and no means of replacing the cartridge. Therefore, it is necessary to replace the entire strut unit. A serviceable strut is designed so the cartridge inside the housing, which provides the shock-absorbing function, can be replaced with a new cartridge. Serviceable struts use a threaded body nut in place of a sealed cap to retain the cartridge.

The shock absorber device inside a serviceable strut is generally wet. This means the shock absorber contains oil that contacts and lubricates the inner wall of the strut body. The oil is sealed inside the strut by the body nut, O-ring, and piston rod seal. Servicing a wet strut with the equivalent components involves a thorough cleaning of the inside of the strut body, absolute cleanliness, and great care in reassembly (including replenishing the strut with oil).

Cartridge inserts were developed to simplify servicing wet struts. The insert is a factory-sealed replacement for the strut shock absorber. The replacement cartridge is simply substituted for the original shock absorber cartridge and retained with the body nut.

Most OE domestic struts are serviced by replacement of the entire unit. There is no strut cartridge to replace. Sealed OE units can also be serviced by replacement with an aftermarket unit that permits future servicing by cartridge replacement.

The use of the strut reduces suspension space and weight requirements. By mounting the bottom of the strut assembly to the steering knuckle, the upper

control arm and ball joint of the traditional suspension are eliminated. In place of the ball joint, the upper mount, which is bolted to the fender panel, is the load-carrying member on MacPherson suspensions.

Strut Mounts

A MacPherson strut has a mount between the top of the strut to the chassis where the strut is supported. These mounts are designed to dampen vibrations as well as secure the strut in position. Often the mounts include a bearing, although some use a bushing. Bearings are most commonly found in front suspensions because the suspension turns or pivots between left and right. Every application is different; however, most applications fall into one of three groupings **(Figure 46–23)**.

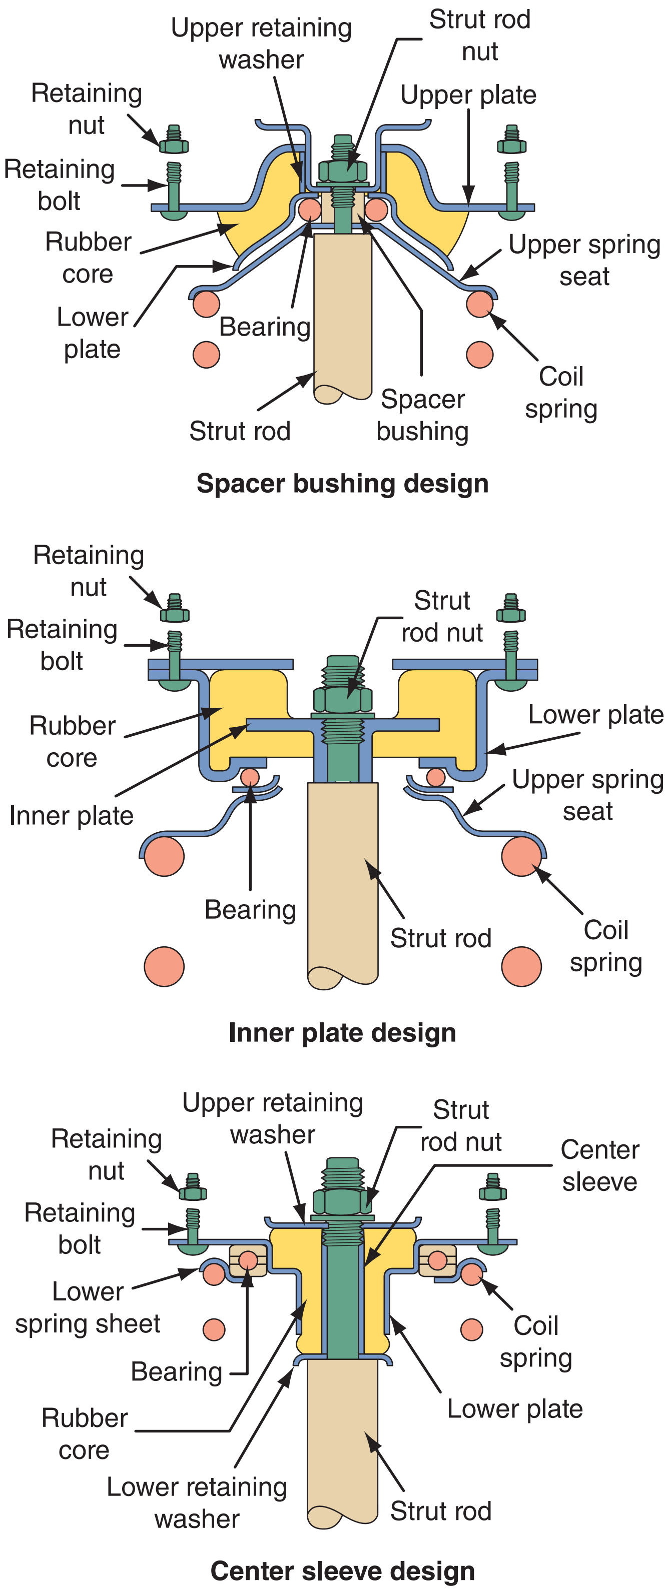

FIGURE 46–23 The different types of upper mounts for a strut.

Spacer Bushing This design has a bearing centered in the mount and a separate inner bushing. The bearing is pressed into the strut mount. The bearing, bushing, and upper plate support the piston. If the bushing is cracked or torn or if the bearing is binding or seized, the strut mount must be replaced.

Inner Plate The inner plate design has a rubber-encased inner plate placed between upper and lower surface plates. The plate prevents the strut piston rod from pushing through the upper or lower surface plate if the inner plate fails.

Center Sleeve The center sleeve design has a center sleeve molded to a rubber bushing. The stem of the strut passes through the sleeve. The bearing is not a part of the strut mount; rather it is a separate unit. To prevent the strut rod from pushing through the mount, upper and lower retainer washers are used. If there are cracks, tears, or other damage to the bushing, the mount should be replaced.

Mount Diagnosis and Service Worn or damaged strut mounts can cause the strut and the strut tower to move independently of one another. This can lead to abnormal noise, a bent or damaged strut, damage to the strut tower, and poor handling. A bad mount may cause a creaking or popping noise. This is caused by too much movement of the strut within the mount. Often the mount is replaced with the strut.

Lower Suspension Components

The lower end of the strut attaches to the steering knuckle, which is sometimes called the hub carrier. A common strut-to-knuckle connection uses mounting flanges that enclose the upper portion of the knuckle **(Figure 46–24A)**. These flanges are built into the strut body and are also used for attaching brake hoses

and ABS wiring. The strut may bolt into an opening in the knuckle **(Figure 46–24B)**. Once inserted, a pinch bolt secures the strut tightly in place.

The suspension's lower mounting position continues to be the frame, as on the traditional suspension, because the lower control arm and ball joint are

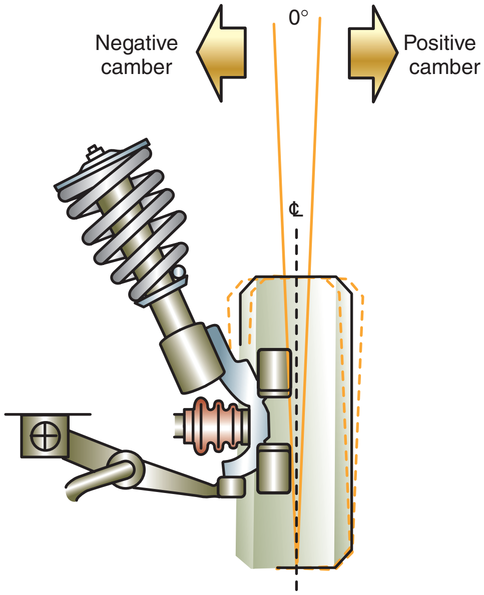

FIGURE 46–25 A front MacPherson strut assembly.

retained **(Figure 46–25)**. As on those suspensions, the control arm serves as the lower locator for the suspension.

MacPherson strut suspensions continue to use sway or stabilizer bars. On models with single-bushing control arms, strut rods or the sway bar can be fastened to the control arm to provide lateral stability.

The lower **ball joint** is a friction or steering ball joint and is used to stabilize the steering and to retard shimmy. The only exception is on modified MacPherson suspensions. In this design, the ball joint becomes the load bearer; the upper mount becomes the steering component. Some designs use two ball joints **(Figure 46–26)** to improve ride and handling.

FIGURE 46–26 Two lower ball joints connect to this steering knuckle.

Springs

Coil springs are used on all strut suspensions. A mounting plate welded to the strut serves as the lower spring seat. The upper seat is bolted to the strut piston rod. A bearing or rubber bushing in the upper mount permits the spring and strut to turn with the motion of the wheel as it is steered.

Short-Long Arm Suspension

The unequal length control arm or **short-long arm (SLA)** suspension system has been common on domestic-made vehicles for many years **(Figure 46–27)**. Each wheel is independently connected to the frame by a steering knuckle, ball joint assemblies, and short upper and longer lower control arms. Because the upper arm pivots in a shorter arc, the top of the wheel moves in and out slightly but the tire's road contact remains constant **(Figure 46–28)**.

One design of an SLA uses a narrow lower control arm, shaped like an "I" **(Figure 46–29)**. A strut rod is used to hold the control arm in place. The strut rod is attached to the control arm close to the steering knuckle and to the frame in front of the wheel assembly. Rubber bushings at the frame mounting allow the strut rod to move a little when the tire hits a bump. The bushing dampens the shock and prevents it from transmitting through the vehicle's frame.

The essential components of SLA systems are the wheel spindle or steering knuckle assembly, control arms, ball joints, shock absorbers, and springs, either coil or torsion bar.

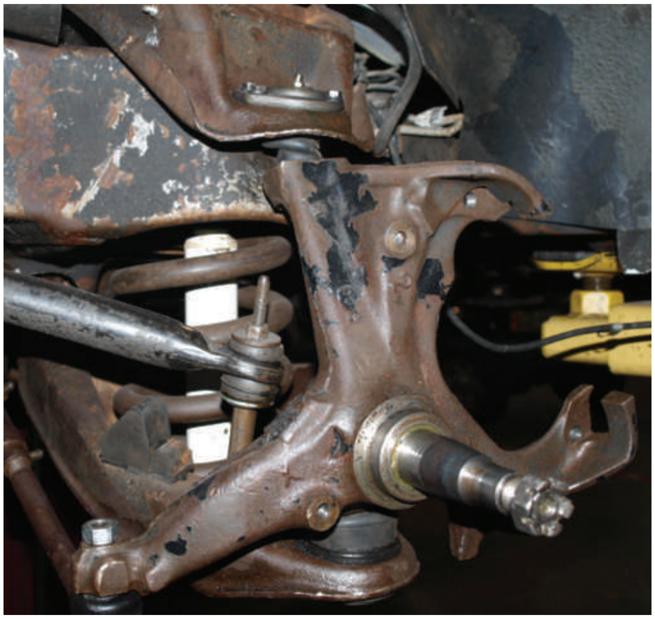

FIGURE 46-27 A typical SLA front suspension.

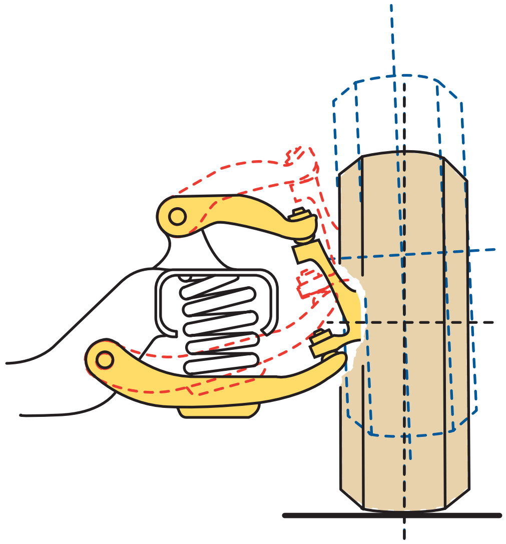

FIGURE 46-28 The movement of the wheel as a short-long arm suspension system moves up and down.

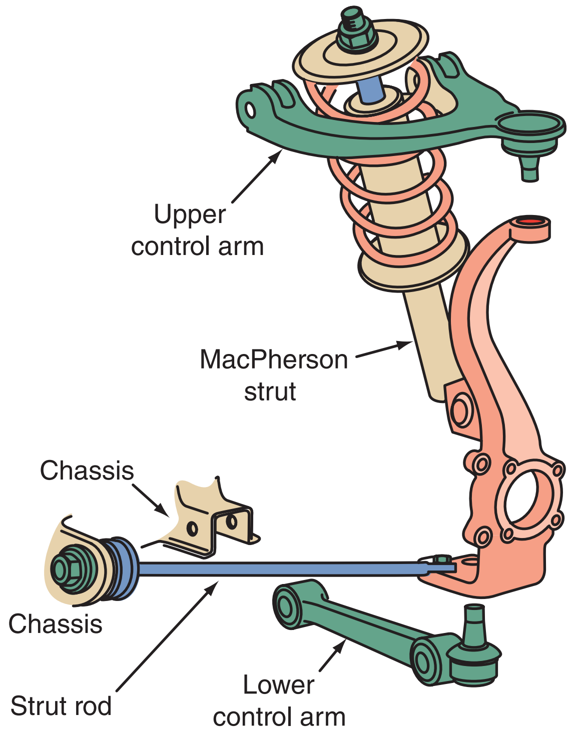

FIGURE 46-29 A FWD suspension system with a narrow lower control arm mounted on a single pivot.

Wheel Spindle A **wheel spindle** assembly consists of a wheel spindle and a steering knuckle. A wheel spindle is connected to the wheel through wheel bearings and is the point at which the wheel hub and wheel bearings are connected. A steering knuckle is connected to control arms. In most cases, a steering knuckle and wheel spindle are forged to form a single piece.

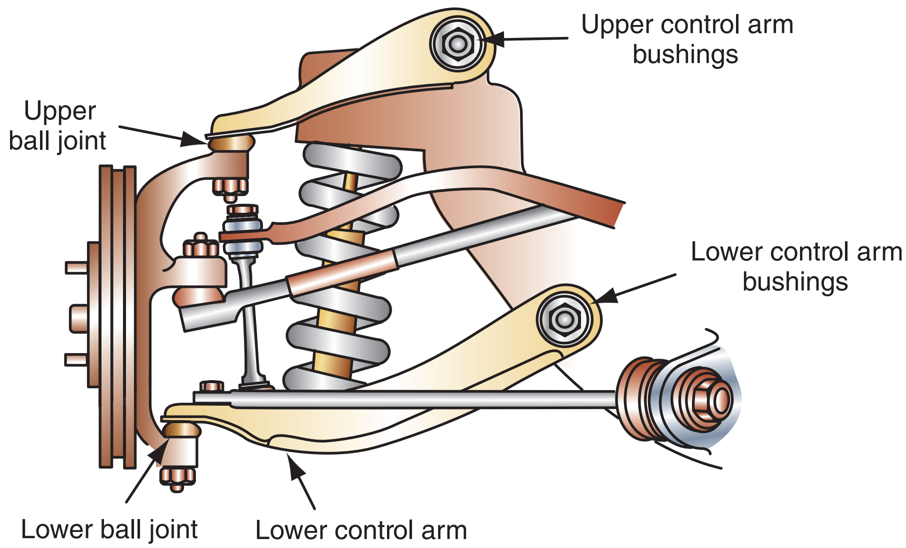

FIGURE 46-30 Ball joint locations in an SLA suspension.

Control Arms The upper and lower **control arms** on the traditional independent front suspension (IFS) function primarily as locators. They fix the position of the system and its components relative to the vehicle and are attached to the frame with bushings that permit the wheel assemblies to move up and down separately in response to irregularities in the road surface. The outer ends are connected to the wheel assembly with ball joints **(Figure 46–30)** inserted through each arm into the steering knuckle.

There are two types of control arms: the wishbone, or double-pivot, control arm and the single-pivot, or single-bushing, control arm **(Figure 46–31)**. The wishbone offers greater lateral stability than the single-pivot arm, which is lighter and requires less space than the wishbone but also requires modifications in suspension design to compensate for the reduced lateral stability. Those modifications are discussed further later in this chapter.

FIGURE 46-31 A front-suspension system with an upper control arm shaped like a "wishbone," which is what this type of suspension is called.

Ball Joints A ball joint **(Figure 46–32)** connects the steering knuckle to the control arm, allowing it to pivot on the control arm during steering. Ball joints also permit up-and-down movement of the control arm as the suspension reacts to road conditions. The ball joint stud protrudes from its socket through a rubber seal that keeps lubricating grease in the housing and keeps dirt out. Some ball joints require periodic lubrication, while most do not. These maintenance-free ball joints move in a prelubricated nylon bearing.

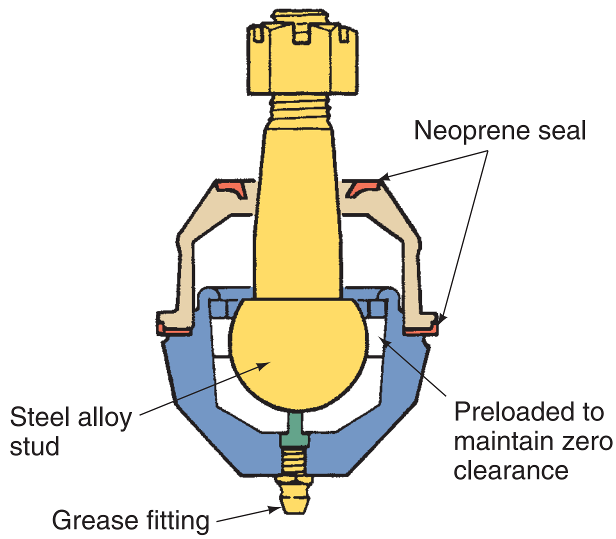

FIGURE 46-32 A typical ball joint.

Ball joints are either load carrying or are followers. A load-carrying ball joint supports the car's weight and is generally in the control arm that holds or seats the spring. Load-carrying joints can be called tension-loaded or compression-loaded ball joints **(Figure 46–33)**. The correct term depends on whether the force of the load tends to push the ball into the socket (compression) or pull it out of the socket (tension).

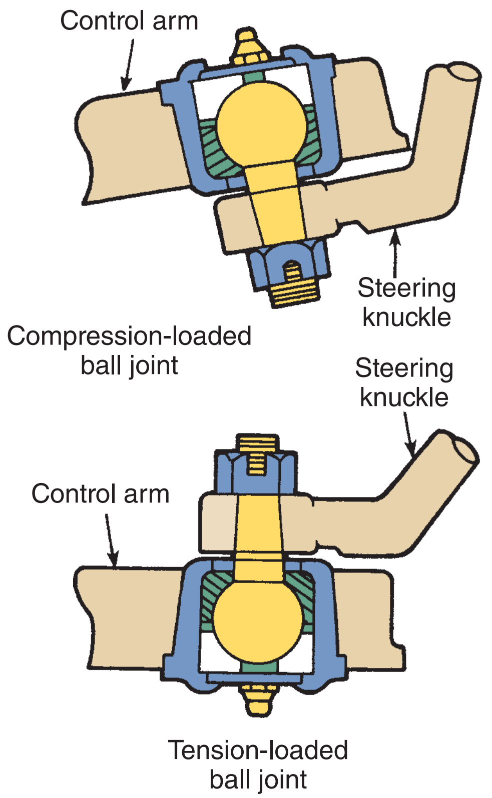

FIGURE 46–33 Two basic types of load-carrying ball joints.

Follower ball joints are often called friction-loaded ball joints. A follower ball joint mounts on the control arm that does not provide a seat for the spring. The follower does not support vehicle weight and does not get the same stress as the load carrier.

Depending on the location of the suspension system's spring, either the upper or lower ball joint will be the load-carrying joint. In a MacPherson strut suspension, there is usually only one ball joint on each side and it is typically a follower. In modified strut suspensions, the ball joint is a load-carrying joint because the spring is positioned between the frame crossmember and the lower control arm.

Some ball joints have wear indicators. As the joint wears, the grease fitting of the joint recedes into the housing. When the shoulder of the fitting is flush with the housing, the joint needs to be replaced **(Figure 46–34)**.

A ball joint is nothing more than a ball-in-socket joint. As long as the ball is firmly in the socket and the ball and/or socket is not worn, the joint will provide a solid connection. Once the ball or socket is worn, the connection becomes sloppy. How the ball is kept in its socket depends on the type of ball joint it is. Load-carrying ball joints rely on the vehicle's weight to keep the ball in the socket **(Figure 46–35)**. As weight is removed from the joint, the ball relaxes in the socket and will feel loose. Follower ball joints are held in place by friction inside the joint. A spring inside the joint typically keeps the ball tight in the socket but allows for some flexibility. This type of joint should never have any play.

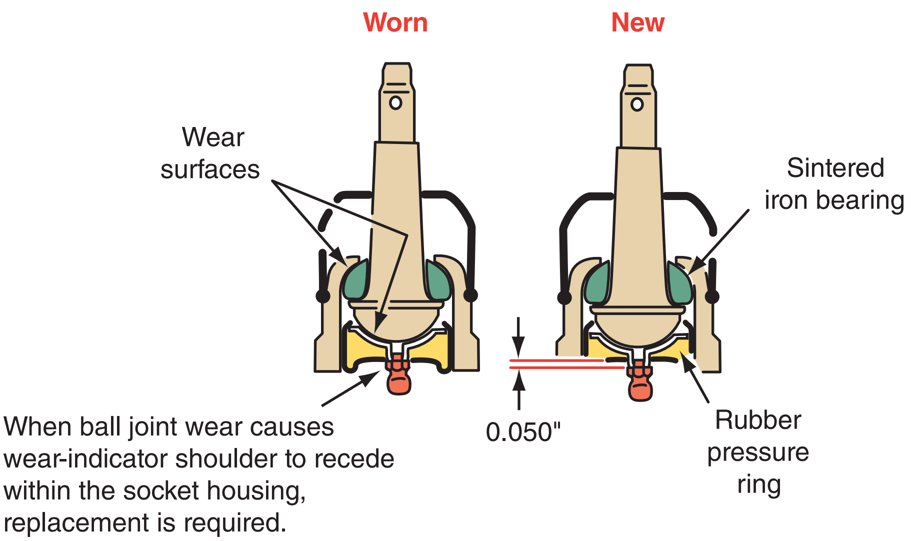

FIGURE 46–34 A wear indicator on a ball joint.

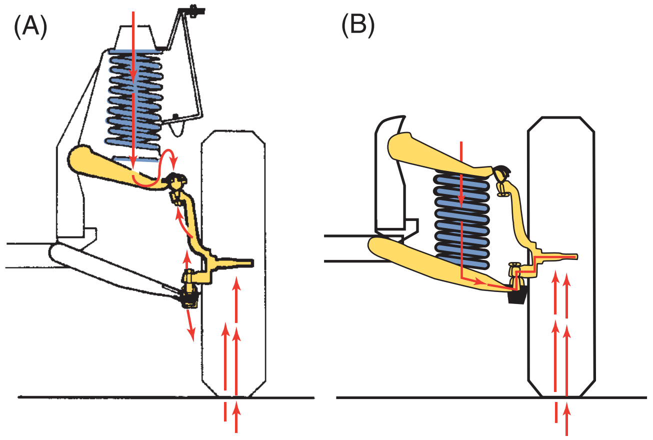

FIGURE 46–35 (A) The upper ball joint is the load-carrying joint. (B) The lower ball joint is the load-carrying joint in this system.

Four-Link or Multilink Front Suspension

A four-link front suspension, also called a multilink suspension, fixes the wheel with four rod-type control arms and the tie-rod **(Figure 46–36)**. The suspension strut supports the vehicle weight against the body via the load-bearing link. By separating wheel attachment and suspension elements, this suspension optimizes ride quality and movement. The influence of drive forces on the steering system is also minimal. This type of suspension is common on both RWD and FWD vehicles due to its compact design and neutral handling qualities.

FIGURE 46–36 A four-link front-suspension system.

FIGURE 46–37 An independent 4WD front-suspension.

Four-Wheel Drive Front Suspensions

Most modern four-wheel drive (4WD) trucks use an independent front suspension. The suspension may use short-long arms and a torsion bar or may use a multilink arrangement **(Figure 46–37)**. Mounting the front differential solidly to the frame and using two short drive axles allows for an independent suspension that improves ride quality compared to older, dependent suspensions. Older 4WD trucks and some new heavy-duty versions use a live axle. While very strong, using a live axle in the front suspension reduces ride quality and handling.

Basic Front-Suspension Diagnosis

Diagnosis of suspension problems should follow a logical sequence. The following procedure can be used on most vehicles; however, it is also best to follow the sequence given by the manufacturer for a specific vehicle.

PROCEDURE

To diagnose a suspension system:

STEP 1 Take the vehicle on a road test and verify the customer's concern.

STEP 2 Inspect the tires. Check their condition and air pressure. Also make sure that the sizes of the tires and wheels are correct.

STEP 3 Inspect the chassis and underbody. Remove any excessive accumulation of mud, dirt, or road deposits. Then:

- Inspect all parts to identify any aftermarket modifications that may have been made.
- Check vehicle attitude for evidence of overloading or sagging. Be sure the chassis height is correct.
- Raise the vehicle off the floor. Grasp the upper and lower surfaces of the tire and shake each front wheel to check for worn wheel bearings.
- Look for loose or damaged front- and rear-suspension parts.
- Check loose, damaged, or missing suspension bolts.
- Check the ball joints for looseness and wear.
- Check the condition of the struts' upper mounts.
- Check the shock absorbers and struts for signs of fluid leakage **(Figure 46–38)** and damage.
- Check all of the mountings for the shocks and struts.
- Check all suspension bushings for looseness, splits, cracks, misplacement, and noises.
- Check the steering mounts, linkages, and all connections for looseness, binding, or damage.
- Check for damaged or sagging springs.
- Check the drive axles for damage and looseness.

STEP 4 If the cause of the customer's concern was found, make the repair as necessary and verify that the repair fixed the problem.

STEP 5 If the cause of the concern was not found, refer to the symptom chart given in the service information and conduct all applicable checks. Then make the repair as necessary and verify that the repair fixed the problem.

SHOP TALK

Often the steering behavior of a vehicle is stated as having oversteer or understeer. Although the terms refer to handing, they actually refer to traction while a vehicle is turning. Oversteer occurs when the vehicle turns more than the driver intends. It occurs when the rear wheels lose traction before the front wheels do. This can result from sudden and hard acceleration or a quick weight transfer to the front during a sudden lift of the accelerator pedal, a stab on the brakes or too much steering input. Understeer occurs when the vehicle turns less than the movement of the steering wheel and it turns wider than the intended path, this happens when the front wheels lose traction before the rear wheels. These characteristics are part of the design of the car and are very difficult to correct; however, they can be corrected.

FIGURE 46–38 Check the shock absorbers for signs of fluid leakage.

Shock Absorber or Strut Bounce Test

With the vehicle on the ground, a quick check, called the bounce test, can be performed to check the operation of the shocks and struts. When the bounce test is performed, the bumper is pushed two or three times downward with considerable weight applied on each corner of the vehicle. The bumper is released after each push and the vehicle should oscillate about 1½ cycles and then settle. One free upward bounce should stop the vertical chassis movement if the shock absorber or strut provides proper spring control. If the vehicle's bumper does more than 1½ free upward bounces, the shock absorber or strut is defective.

A shock that does not bounce excessively in the shop still may not respond properly during operation on the road. A test drive should be performed over various road conditions to fully evaluate the dampening ability of the shock.

Excessive Body Roll

If a vehicle leans or rolls excessively during corners, the sway bar links are likely broken. Broken links can also cause noise over bumps and while turning.

Noises

Abnormal noises from the suspension system can be caused by a number of problems. Tire noise varies with road surface conditions, whereas differential noise is not affected when various road surfaces are encountered. Uneven tread surfaces may cause tire noises that seem to originate elsewhere in the vehicle. These noises may be confused with differential noise. Differential noise usually varies with acceleration and deceleration, whereas tire noise remains more constant in relation to these forces. Tire noise is most pronounced on smooth asphalt road surfaces at speeds of 15 to 45 mph (24 to 72 km/h).

Rattling on road irregularities can be caused by worn shock absorber bushings or grommets, worn spring insulators, a broken coil spring or broken spring insulators, worn control arm bushings, worn stabilizer bar bushings, and worn strut rod grommets, worn leaf spring shackles and bushings, and worn torsion bars, anchors, and bushings. Dry or worn control arm bushings may cause a creaking or squeaking noise on irregular road surfaces.

Chatter while cornering can be caused by worn upper strut mounts. Front strut noise on sharp turns or during suspension jounce may be caused by interference between the coil spring and the strut tower **(Figure 46–39)** or between the coil spring and

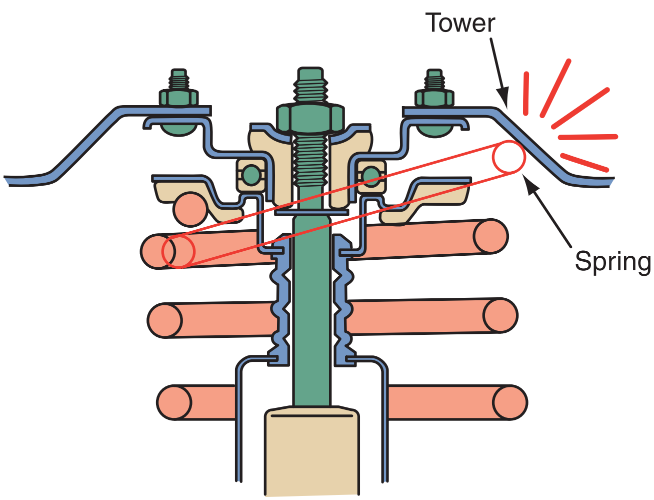

FIGURE 46–39 Coil spring to strut tower interference.

SHOP TALK

Before visual inspection or suspension height measurements can be performed, the vehicle must be on a level surface. Tires must be at recommended pressures; gas tank must be full; and there should be no passenger or luggage compartment load. Beginning at the rear bumper, jounce the car up and down several times. Proceed to the front bumper and repeat, releasing during same cycle as rear jounce.

the upper mount. Worn upper strut mounts or bearings can also cause binding and poor steering return.

Knocking noises can be caused by broken sway bar links, worn and loose ball joints, worn control arm, strut rod, or radius arm bushings. Severely worn struts or shocks can also cause knocking sounds, especially over very bumpy roads.

Chassis Height Specifications

A quick overall visual inspection detects any obvious sag from front to rear or from side to side. Under the car, at the level of the two ends of the control arms, check for out-of-level, damaged, or worn rubber bumpers, or shiny or worn spring coils. All indicate weak coil springs.

USING SERVICE INFORMATION

For the most accurate measurement of chassis height, use the service information to check against the manufacturer's recommendations for the specific model. Photo Sequence 42 shows the typical procedure for checking vehicle ride height. Be careful. The measurement points vary from one model to another even if manufactured by the same company. When coil-spring wear is suspected, it might be necessary to load the vehicle to the manufacturer's suggested capacities and measure at the designated points.

A more accurate inspection reveals less obvious problems by measuring heights at specific points on each side of the suspension system.

Front-Suspension Component Servicing

Each major component of the suspension system needs to be carefully checked. Each has its own procedure for doing this as well as the service procedures. The only maintenance required on suspension systems is a periodic chassis lubrication. If the owner has failed to have this done, many problems can result. Very few vehicles require any periodic chassis lubrication any more as nearly all suspension and steering components are sealed and greased for life. However, if a vehicle has had components replaced, such as ball joints or steering sockets, these parts will likely need to be greased.

GO TO Chapter 8 for details on how to lubricate the chassis.

Coil Springs

Coil springs require no adjustments and are basically trouble-free. However, the constant compression and extension of the spring can lead to a loss of elasticity and cause spring sag. Coil springs then need to be replaced. A weak spring upsets vehicle trim height, which can cause incorrect wheel alignment, abnormal steering, poor headlight aim, poor braking, increased tire wire, reduced traction, and a decrease in the service life of U-joints and shocks.

Coil springs can also break. This is often due to vehicles being overloaded or rusted. When a vehicle carries more weight than it was designed to carry, the springs can break from being overly compressed.

A vital step in replacing a coil spring is to identify the correct replacement. Begin by looking for the OEM part number, which is normally on a tag wrapped around a coil. Often, this tag falls off before replacement is necessary. If a set of aftermarket springs has been installed, the part number might be stamped on the end of the coil. Next, determine what types of ends the coils springs have. There are three types of ends used in automotive applications: full wire open, tapered wire closed, and pigtail. Springs with full wire open ends are cut straight off and sometimes flattened or ground into a D or

square shape. Tapered wire closed ends are wound to ensure squareness and ground into a taper at the ends. Pigtail ends are wound into a smaller diameter at the ends.

The final step is to check all available service information. To do this, it is necessary to know the make, year, model, body style, and engine size, and if the vehicle is equipped with air conditioning. In some cases, it is also good to know the type of transmission, seating capacity, and other specifics that add extra weight to the vehicle. In most parts catalogs, springs are listed by vehicle and VIN in two sections: front and rear. Springs should always be replaced in pairs.

Removing a Spring To remove a coil spring, raise and support the vehicle by its frame. Let the control arm hang free. Remove wheels, shock absorbers, and stabilizer links. Disconnect the outer tie-rod ends from their respective arms. Remove the brake caliper and support it with a wire or bungee cord so it does not hang on the brake hose.

Unload the ball joints with a roll-around floor jack. Jack under the lower control arm from the opposite side of the vehicle. This allows the jack to roll back when the control arm is lowered. Position the jack as close to the lower ball joint as possible for maximum leverage against the spring.

The spring is ready for the installation of the spring compressor **(Figure 46–40)**. There are many different types of spring compressors. One type uses a threaded compression rod that fits through two plates, an upper and lower ball nut, a thrust washer, and a forcing nut. The two plates are positioned at either end of the spring. The compression rod fits through the plates with a ball nut at either end. The upper ball nut is pinned to the rod. The thrust washer and forcing nut are threaded onto the end of the rod. Turning the forcing nut draws the two plates together and compresses the spring.

In some cases, it is necessary to break the tapers of both upper and lower ball joints so the steering knuckle can be moved to one side **(Figure 46–41)**. If the vehicle is equipped with a strut rod, this must be disconnected at the lower control arm. Push the control arm down until the spring can be removed. If necessary, a pry bar can be used to remove the spring from its lower seat. Remove the spring and compressor.

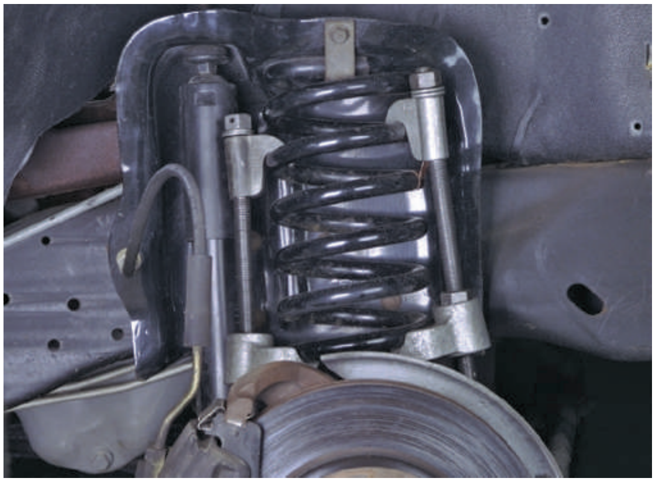

FIGURE 46–40 A coil-spring compressor is used to compress the spring before disconnecting some suspension parts.

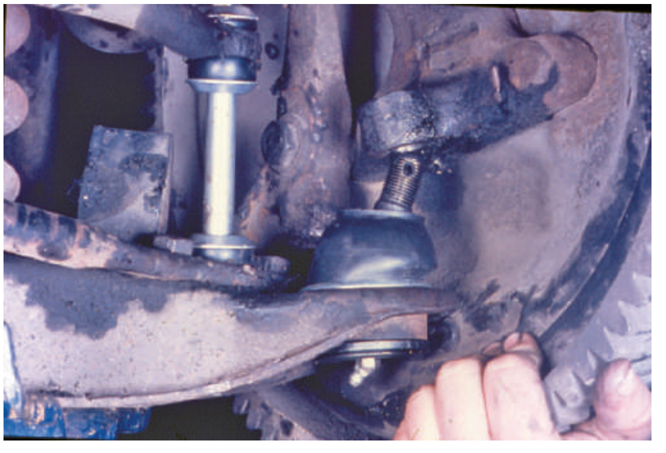

FIGURE 46–41 At times the steering knuckle must be disconnected from the lower and/or ball joint in order to remove a spring.

If the same spring is to be reinstalled, leave the compressor in position. If a new spring is to be used, slowly release the pressure on the tool by backing off the forcing nut. Compress the new spring prior to installing it.

Torsion Bars

Torsion bars are subjected to many of the same conditions affecting coil springs. Periodic adjustment of the torsion bars is necessary to maintain the proper height. Replacement is sometimes necessary because of breakage. It should be noted that the bars are not interchangeable from side to side.

FIGURE 46–42 A torsion bar adjuster.

Removing a torsion bar often requires a special tool used to unload the bar. Begin by lifting and supporting the vehicle by the frame. Remove any covers or plates covering the torsion bar adjuster **(Figure 46–42)**. Measure and record or mark the adjuster bolt before loosening it. This measurement will be used when installing the bar and setting the tension. Install the torsion bar tension relief tool and tighten the tool until the torsion bar adjuster is loose. Remove the adjuster and loosen the tool until tension is off of the bar. Remove the tool and then remove the torsion bar from the control arm.

Install the new torsion bar and apply tension using the tool. Tighten until the new adjustment bolt can be installed and set the bolt at the depth measured on the old bolt before removal. Loosen and remove the tool. Once the torsion bar is installed, set the vehicle back on the ground, bounce it several times to settle the suspension, and measure the ride height. Height inspection and measurements for vehicles with torsion bar suspensions are often the same for coil springs. Procedures for adjusting torsion bars are given in the service information. If ride height is incorrect, adjust the torsion bar until the height is within specifications. Once ride height is correct, check the wheel alignment.

Ball Joints

Begin your inspection of a ball joint by checking to see if the ball joint has a wear indicator on it. If it does, check the placement of the grease fitting. If it is recessed, the ball joint is worn and should be replaced. On some vehicles it is recommended that you check to see if the grease fitting can wiggle in the ball joint. If it does, the ball joint should be replaced. Always check the service information when checking ball joints.

Look carefully at the joint's boot. A damaged boot or joint seal will allow lubricant to leak out and allow dirt to enter and contaminate the lubricant. If the boot is damaged, the ball joint should be replaced.

If no boot damage is evident, gently squeeze the boot. If the boot is filled with grease, it will feel somewhat firm. If the joint has a grease fitting and appears not to be filled with grease, use a grease gun and refill the joint. Fill the joint until fresh grease is seen flowing out of the boot's vent. If too much grease is forced into the joint or it is forced in too quickly, the boot can unseat or tear.

Ball joints should be checked for excessive wear. Load-carrying joints may have some slop when the weight of the vehicle is taken off them. Follower joints should never have play. To check a load-carrying joint, it must be unloaded.

When the coil spring is on the lower control arm, raise the vehicle by jacking under the control arm as close to the ball joint as possible. This gives the maximum amount of leverage against the spring. The ball joint is unloaded when the upper strike out bumper is not in contact with the control arm or frame. A quick check for looseness can be made by using a pry bar between the tire and the ground. To find out if the ball joint is loose beyond manufacturer's specifications, use an accurate measuring device. The following checking procedures demonstrate the use of a dial indicator. The dial indicator is a precision instrument and should be handled carefully to prevent damage. The mounting procedure for the checking tool might vary depending on the style of ball joint used on the vehicle. Manufacturer's tolerances can be axial (vertical), radial (horizontal), or both. To conduct these checks, follow these procedures.

Typical Radial Check For a radial check, attach a dial indicator to the control arm of the ball joint being checked. Position and adjust the plunger of the dial indicator against the edge of the wheel rim nearest to the ball joint being checked. Slip the dial ring to the zero marking. Move the wheel in and out and note the amount of ball joint radial looseness registered on the dial **(Figure 46–43)**. The procedure for checking the radial movement of a lower ball joint on a MacPherson strut front suspension is shown in Photo Sequence 43.

Typical Axial Check For an axial check, first fasten the dial indicator to the control arm, then clean off the flat on the spindle next to the ball joint studnut. Position the dial indicator plunger on the flat of the spindle and depress the plunger approximately 0.350 inch. Turn the lever to tighten the indicator in

place. Pry the bar between the floor and tire. Record the reading **(Figure 46–44)**.

If the ball joint looseness reading on the dial indicator exceeds manufacturer's specifications, the ball joint should be replaced.

When the load-carrying ball joints are on the upper control arm (spring mounted on the upper arm), place a steel wedge between the bottom of the upper control arm and the frame. Next, raise the vehicle by its frame to unload the ball joints and hold them in their normal position. Pry up on the tire to check for play in the load-carrying joint. To determine the condition of the non-load-carrying (or follower) ball joint, vigorously push and pull on the tire, while watching the ball joint for signs of movement. Refer to the manufacturer's specifications for tolerances.

Rotational Torque Test

Ball joints on many Toyota products have a specification for the rotational tightness of the ball joint. To check, move the stud back and forth several times, turn the stud by hand, then attach a torque wrench to the stud **(Figure 46–45)**. Rotational torque is then compared to specifications. Typical specs are less than 31 in-lbs.

Inspection of Wear Indicators Wear-indicator-type ball joints must remain loaded to check for wear. The vehicle should be checked with the suspension at curb height. The most common type has a small-diameter boss, which protrudes from the center of the lower housing. As wear occurs internally, this boss recedes very gradually into the housing. When it is flush with the housing, the ball joint should be replaced. To remove and install a ball joint, follow the procedure given in the service information.

Replacing Ball Joints

Ball joints are mounted to the control arm in one of four basic ways: rivets, bolts, press fit, and threaded. To replace a ball joint, safely raise and support the vehicle. Depending on the vehicle and spring location, you may need to support the control arm. In most cases, remove the brake caliper and support it using a wire or bungee cord. Next, remove the ball joint to steering knuckle nut and separate the knuckle from the joint. Once the knuckle is out of the way, you will have access to the ball joint.

Many ball joints are riveted in place at the factory. Replacing these joints requires drilling or cutting out the rivets. Once the rivets are removed, the new ball joint is bolted in the control arm. Bolted in ball joints are removed by simply removing the bolts and nuts securing it to the arm. Once the new joint is installed, torque the bolts and nuts to specifications.

The most common method is press fit. Some manufacturers require you to replace the entire control-arm assembly if a ball joint is to be replaced. In these cases, the ball joint and control arm are made as a single assembly and individual parts are not available.

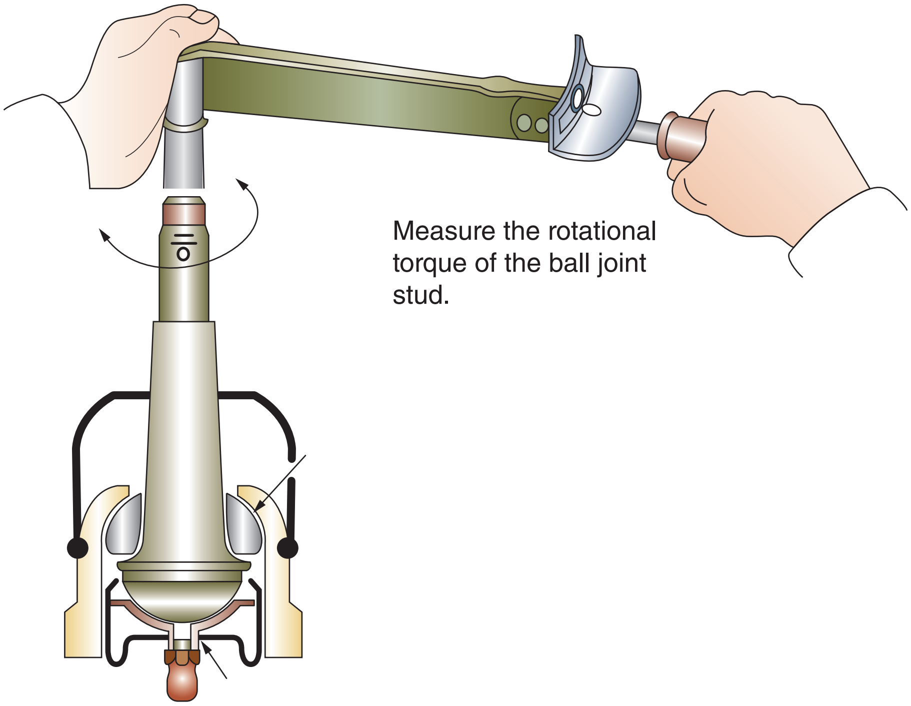

FIGURE 46-45 Checking rotational torque.

Press-fit ball joints are typically removed and installed using a special ball joint press **(Figure 46–46)**. While pressing the ball joint out of or into the control arm, make sure you do not damage the arm.

A few vehicles use threaded ball joints. In this style, external threads are formed in the outside of the ball joint housing. The joint threads into the control arm. To replace it, remove the steering knuckle and unscrew the ball joint. Install the new joint and torque it to specifications.

Once the new ball joints are installed, reinstall the steering knuckle and torque the ball joint nut to specifications. If a castle nut is used and the hole in the ball joint stud does not align with the hole in the nut, tighten the nut until the two align. Install a new cotter pin and bend one or both prongs so that the pin cannot back out of the joint.

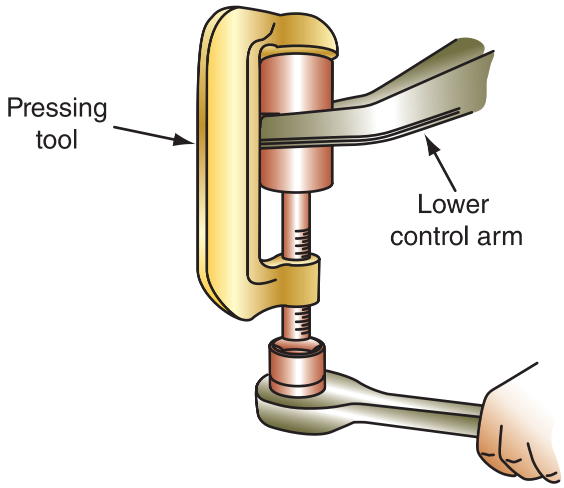

FIGURE 46-46 Pressing in a new ball joint.

Warning! Never use heat to remove a ball joint.

Control Arm Bushings

Visually inspect each rubber bushing for signs of distortion, movement, off-center condition, and presence of heavy cracking. Check metal bushings for noise and loose seals.

To remove the control arm bushings, raise the vehicle and support the frame on safety jack stands. Remove the wheel assembly. Install a spring compressor on the coil spring.

Disconnect the ball joint studs from the steering knuckle as described previously. Remove the bolts attaching the control-arm assembly to the frame and remove the control arm.

Bushings are pressed in and out of their bores by using special tools. A special tool is installed over the bushing **(Figure 46–47)** after the correct size adapter for the tool has been selected. Tightening

the tool pushes the bushing out of the control arm. The same process is used to press a new bushing into the control arm. As the special tool is tightened, the bushing moves into its bore. When installing new bushings, make sure they stay straight while they are being pressed in.

Once the new bushings are started into the control arm, measure and mark the center between mounting holes and center the control arm. Now, alternately press in the bushings on each side, keeping the reference marks aligned. This ensures the shaft is not off center, causing binding. End cap nuts or bolts should not be torqued until the vehicle is at curb height and the suspension has been bounced and allowed to settle out.

Rebolt the control arm and tighten the bolts to specifications, then install the coil spring into position. Install the ball joint studs into the control arms. Remove the coil-spring compressor. Install the wheel assembly and lower the car. Road test the car, retighten all bolts, and set wheel alignment.

Strut Rod Bushings

Except in the case of accidental damage, the strut rod itself is rarely replaced. Rather, it is the bushing that wears, deteriorates, and needs replacement. To replace the bushings, remove the nuts and bolts securing the strut rod to the frame and control arm. Remove the bushings and washers and replace with new and in the correct order. Torque all the fasteners to specifications. Depending on the suspension arrangement, removing and replacing the strut rod bushings require checking and adjusting caster.

Sway Bar Bushings and Links

These bushings anchor the sway bar securely to the vehicle frame and the control arms on each side. The condition of the bushings affects the performance of the bar. Visual inspection of mounting bushings indicates if the bushings are worn, have taken a permanent set, or are possibly missing. Also check the sway bar links. Any damage indicates that they should be replaced.

Sway bar links on older vehicles typically use a long bolt, washers, bushings, a spacer, and a nut. The link is assembled between the control arm and sway bar **(Figure 46–48)**. Over time, the links rust and break. Install a sway bar link kit, making sure the bushings and washers are installed in the correct positions. Tighten the bolt and nut to specifications to prevent overtightening and collapsing the bushings.

FIGURE 46–48 A broken sway bar link.

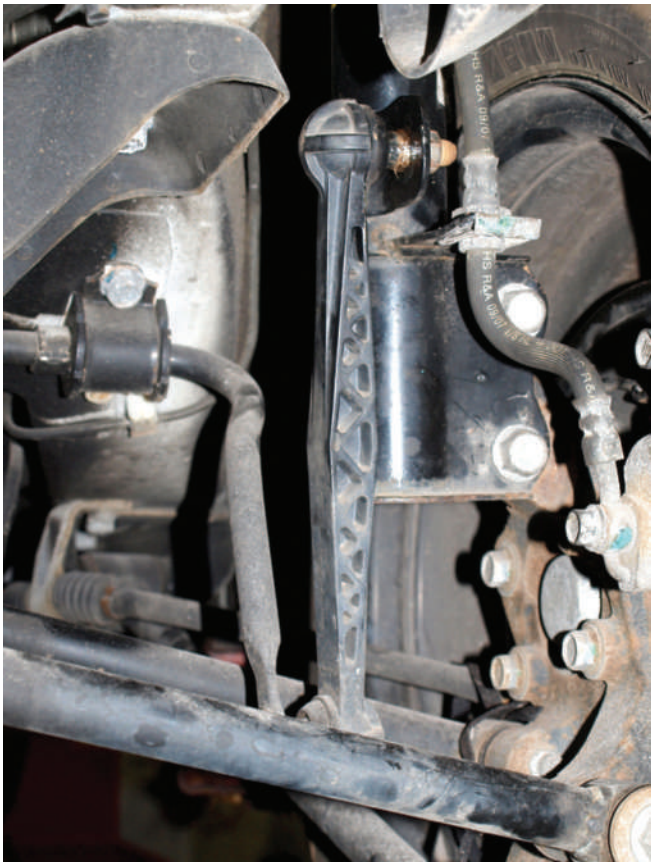

FIGURE 46–49 An example of a sway bar link.

Most vehicles now use plastic or metal links with ball socket joints on the ends. The ball sockets connect the link to the sway bar and control arm or strut **(Figure 46–49)**. This type of link typically does not come without destroying the ball socket. This means that if the link needs to be removed, such as when replacing a strut, the link will likely need to be replaced also as the ball sockets do not usually separate without damage.

Shock Absorbers

A shock absorber that is functioning properly ensures vehicle stability, handling, and rideability. Most motorists fail to notice gradual changes in the operation of their cars as a result of worn shock absorbers. Some common indications of shock absorber failure follow:

- Steering and handling are more difficult.
- Braking is not smooth.
- Bouncing is excessive after bumps and stops.
- Tire wear patterns are unusual, especially cupping.
- Springs are bottoming out.

Warning! Gas-pressurized shock absorbers will extend on their own and can create a dangerous situation. Never apply heat or flame to the shock absorbers during removal; the heat will cause the gas to expand and the shock will quickly extend. Before disposing of used gas-pressurized shocks and struts, refer to the manufacturer's service information regarding the release of gas pressure. This usually requires drilling a small hole in a specific location in the shock body to release the pressure.

Shock absorbers should be inspected for loose mounting bolts and worn mounting bushings. If these components are loose, they will rattle, and replacement of the bushings and bolts is necessary. The upper mounts of struts should also be carefully checked.

In some shock absorbers, the bushing is permanently mounted in the shock, and the complete unit must be replaced if the bushing is worn. When the mounting bushings are worn, the shock absorber will not provide proper spring control.

Vibrations set up by a worn shock absorber can cause premature wear in many of the undercar systems. They can cause wear in the front and rear component parts of the suspension system, the linkage component parts of the steering system, and the U-joints and motor or transmission mounts of the driveline. Also, vibrations can cause unnatural wear patterns on the tires.

When replacing shocks, refer to the service information. Some rear shocks are mounted into the passenger compartment or trunk, requiring extra caution during replacement. For most front shocks, remove the shock's lower mounting bolt(s) and then remove the upper mount. If the shock mount uses bushings, install the new bushings on the shock to prevent metal-on-metal contact. Install the shock and torque all fasteners to specs.

Rear shock replacement may require using a jack to support the rear axle or suspension but the replacement procedure is basically the same as for front shock replacement. If the old shocks are gas-pressurized, refer to the procedures for releasing the gas before disposing of the shock.

A shock absorber can be bench tested. First, turn it up in the same direction it occupies in the vehicle. Then extend it fully. Next, turn it upside down and fully compress it. Repeat this operation several times. Install a new shock absorber if a lag or skip occurs near mid-stroke of the shaft's change in travel direction, or if the shaft seizes at any point in its travel, except at the ends. Also, install a new shock absorber if noise, other than a switch or click, is encountered when the stroke is reversed rapidly, if there are any leaks, or if action remains erratic after purging air.

MacPherson Strut Suspension

The MacPherson strut suspension system is based on a triangular design. The strut shaft is a structural member that does away with the upper control arm bushings and the upper ball joint. Since this shaft is also the shock absorber shaft, it receives a tremendous amount of force vertically and horizontally. Therefore, this assembly should be inspected very closely for leakage, bent shaft, and poor damping.

To remove and replace the MacPherson strut, proceed as shown in Photo Sequence 44.

During the disassembly of the strut, make sure you check the strut pivot bearing **(Figure 46–50)**. Move the bearing with your hand. If the bearing is hard to move or seems to bind, it must be replaced. When replacing the bearing, make sure the correct side is up. Manufacturers normally mark the up side with paint or some other marking. Make sure you check all rubber insulators for deterioration and other damage and replace them if necessary. Also make sure you mark the eccentric camber bolts before loosening them. Returning the bolts in the same location will help maintain the correct camber angle after reassembly. Also replace all cotter pins in the suspension and align the wheels after everything is reassembled.

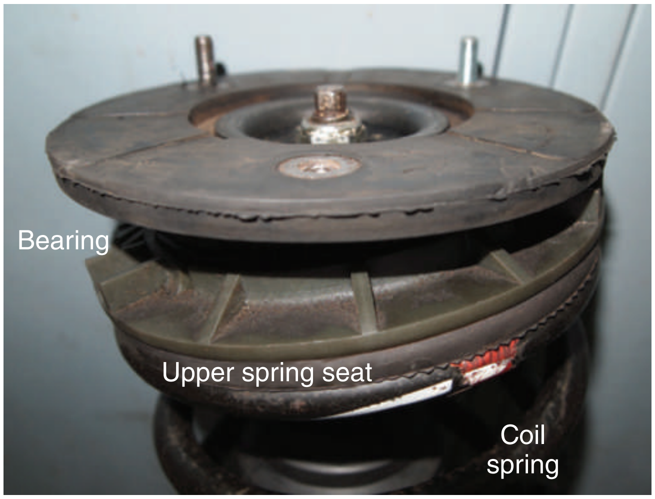

FIGURE 46–50 Check the strut's pivot bearing for free movement.

Rear-Suspension Systems

There are three basic types of rear suspensions: live-axle, semi-independent, and independent. There are distinct designs of each, but the types of components and the principles involved are the same as on front-suspension systems described earlier in this chapter. Live-axle suspensions are found on rear-wheel drive (RWD) cars, trucks, vans, and the front of many four-wheel drive (4WD) trucks. Semi-independent systems are used on front-wheel drive (FWD) vehicles. Independent suspensions can be found on both RWD and FWD vehicles, as well as 4WD cars.

Live-Axle Rear-Suspension Systems

This traditional rear-suspension system consists of springs used in conjunction with a live-axle (one in which the differential axle, wheel bearings, and brakes act as a unit). The springs are either of leaf or coil type. Air springs are used on some older vehicles.

Leaf Spring Live-Axle System Two springs—either multiple-leaf or monoleaf—are mounted at right angles to the axle and along with the shock absorbers, are positioned below the rear-axle housing. The front of the two springs is attached to brackets on the vehicle's frame by a bolt and bushing inserted through the eyes of the springs. While the bushing allows the spring to move, it isolates the rest of the vehicle from noisy road vibrations.

The center of each leaf spring is connected to the rear axle housing with U-bolts. Rubber bumpers are located between the rear-axle housing and frame or unit body to dampen severe shocks. The rear eye pivot bushings are held to the frame with shackles, which attach to the springs by a bolt and bushing **(Figure 46–51)**.

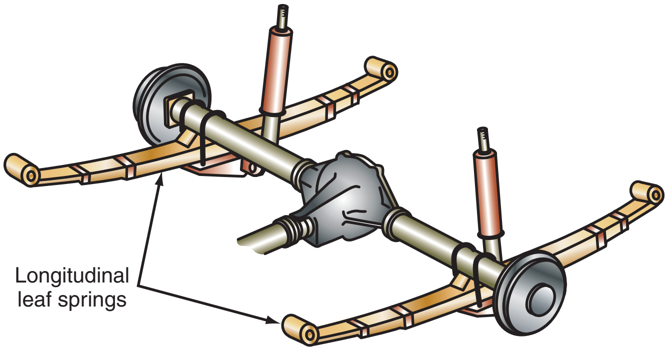

FIGURE 46–51 A typical rear suspension with a live axle.

There are some disadvantages to the live-axle suspension system. First, this design has a large amount of unsprung weight. Another drawback is the instability caused by the use of a solid axle. Since both rear wheels are connected to the same axle, movement up or down by one wheel affects the other. Consequently, poor traction results because both wheels are pushed out of alignment with the road. Under severe acceleration, this type of suspension is subject to axle tramp, a rapid up-and-down jumping of the rear axle due to the torque absorption of the leaf springs. This condition can break spring mounts and shock absorbers and cause premature wear of wheel bearings. Axle tramp is reduced by mounting shock absorbers on the opposing sides (front and back) of the axle. Some heavy-duty vehicles have two-stage springs that allow the vehicle to ride comfortably with both a light or heavy load.

Coil-Spring Live-Axle System Some vehicles use two coil springs at the rear with a live rear axle. Because coil springs can only support weight and have little axle-locating capability, such vehicles need forward and lateral control arms or links. This type of suspension is called the link-type rigid axle.

The coil springs, located between the brackets on the axle housing and the vehicle body or frame, are held in place by the weight of the vehicle and sometimes by the shock absorbers **(Figure 46–52)**. The control arms are usually made of channeled steel and mounted with rubber bushings. Accelerating, driving, and braking torque are transmitted through three or four control arms, depending on the design. Two forward links are always used, but either one or two lateral links can be found on individual models. Trailing arms mount to the underside of the axle, and run forward at a 90-degree angle to the axle to brackets on the car frame. Rubber bushings

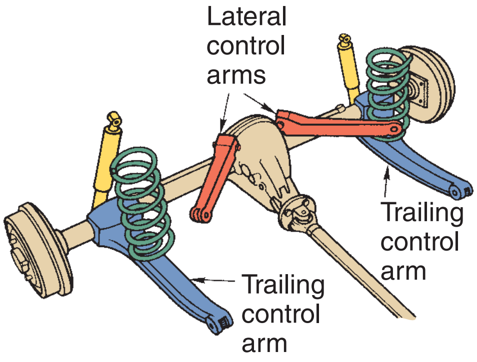

FIGURE 46–52 A typical live-axle suspension with coil springs.

are used at mounting locations to permit up-and-down movement of the arms and to reduce noise and the effect of shock.

Some rear-axle assemblies are connected to the body by two lower control arms and a track bar. A single torque arm is used in place of upper control arms and is rigidly mounted to the rear-axle housing at the rear and through a rubber bushing to the transmission at the front. A few manufacturers are using Watts links in their rear suspensions **(Figure 46–53)**. A Watts link is used to limit rear-axle motion from side to side.

Live-Axle Suspension System Servicing Typical service to both coil-spring and leaf-spring systems include the replacement of shock absorbers or springs. Bushings, shackles, or control arms do not need replacement frequently. Always follow the procedures outlined in the service information whenever servicing the rear suspension.

P44-10 Reinstall the strut assembly into the car. Make sure all bolts are properly tightened and in the correct locations.

Semi-Independent Suspension

A semi-independent suspension system is used on many front-wheel drive models. On some, the suspension position is fixed by an axle beam, or crossmember, running between two trailing arms. Although there is a solid connection between the two halves of the suspension because of the axle beam, the beam twists as the wheel assemblies move up and down. The twisting action not only permits semi-independent suspension movement, but it also acts as a stabilizer. Frequently, a separate shock and spring trailing arm system is also used. In either an integrated or separate shock system, each rear wheel is independently suspended by a coil spring.

A coil spring and shock absorber–strut assembly are ordinarily used with this suspension system. The bottom of the strut is mounted to the rear end of the trailing arm. The top is mounted to the reinforced inner fender panel. Braking torque is transmitted through the trailing control arms and struts. The arms and struts also maintain the fore and aft, and lateral positioning of the wheels. A track bar is also used on some trailing arm suspension systems. The track bar helps to reduce sideways movement of the axle.

Semi-Independent Suspension System Servicing

As in most rear-system servicing, the first step is to remove the shock absorber. It is important to remember not to remove both shock absorbers at one time unless the axle is supported. Suspending the rear axle at full length could result in damage to the brake lines and hoses. The servicing of a semi-independent suspension system usually involves the removal and reinstallation of shock absorbers, springs, insulators, and control arm bushings. Follow the procedures given in the vehicle's service information.

Warning! When removing the rear springs, do not use a twin-post hoist. The swing arc tendency of the rear-axle assembly when certain fasteners are removed might cause it to slip from the hoist. Perform this operation on the floor if necessary.

Independent Suspension

Independent suspensions can be found in large numbers on FWD, RWD, AWD, and even 4WD vehicles. The introduction of independent rear suspensions was brought about by the same concerns for improved traction ride that prompted the introduction of independent front suspensions. If the wheels can move separately on the road, traction and ride are improved.

Independent coil-spring rear suspensions can have several control arm arrangements. For example, A-shaped control arms are sometimes employed. When the wide bottom of a control arm is toward the front of the car and the point turns in to meet the upright, they are called trailing arms **(Figure 46–54)**. When the entire A-shaped control arms are mounted at an angle, they are known as semitrailing control arms or multilink suspensions. Coil springs are used between the control arm and the vehicle body. The control arms pivot on a crossmember and are attached at the other end to a spindle. A shock absorber is attached to the spindle or control arm.

Some vehicles use a rear-suspension system that uses a lower control arm and open driving axles. A crossmember supports the control arms, while the tops of the shock absorbers are mounted to the body. The springs are set in seats at the bottom and top of the crossmember.

A few cars use only lower control arms, but substitute a wishbone-shaped subframe for the upper control arms. Two torque arms transfer the rear-end torque to the subframe. In fact, many cars are now featuring rear double-wishbone suspension **(Figure 46–55)**. Torque loads create bushing and control arm deflection during braking, cornering, acceleration, and deceleration. It is

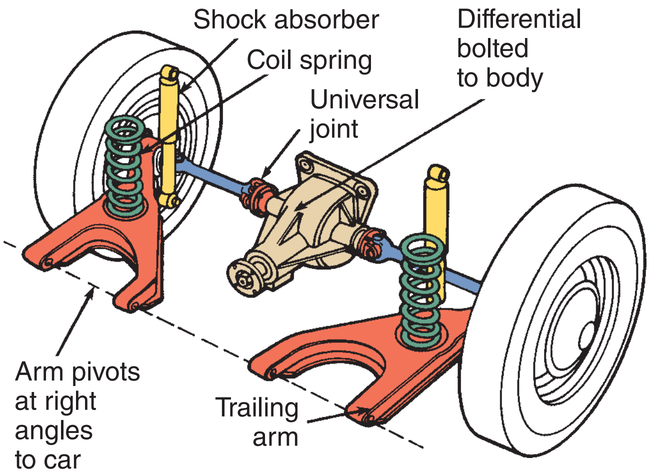

FIGURE 46–54 Trailing arms are often used with independent rear suspensions.

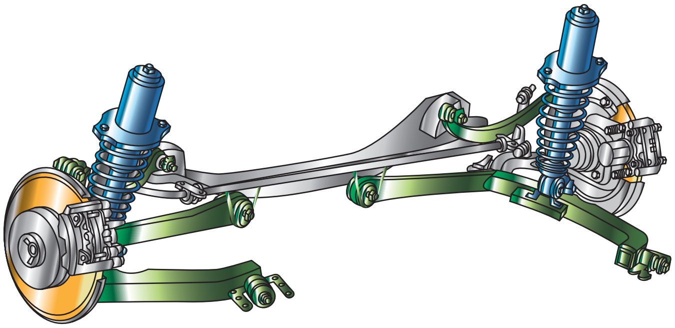

FIGURE 46–55 A double wishbone rear suspension.

interesting to note this rear-suspension system allows for a small amount of toe-in change to enhance straight line stability. The toe-in change during cornering leads to quicker and more responsive turning. The rear-suspension system can also be tuned to ensure minimal dive under braking and minimal squat under acceleration.

Currently, struts are replacing conventional shock absorbers in rear independent-suspension systems. One of the latest strut rear-suspension designs used by car manufacturers is shown in **Figure 46–56**.

On this type of system, the spindle is used to secure the strut, the outer ends of two of the four control arms, the rear ends of the tie-rods, and a rear wheel. The control arms contain bushings of different sizes at their outer ends. The ends with the smaller bushings attach near the body centerline. The ends with the larger bushings attach at the spindle. (When replacing control arms, it is mandatory that offsets at their outer ends and the flanges on the arms face in the direction prescribed in the manufacturer's service information.) This system is also called the nonmodified MacPherson strut system.

FIGURE 46–56 A strut-based rear-suspension system.

The modified MacPherson strut rear suspension is common for vehicles with front-wheel drive. The major components on each side of the vehicle are a modified MacPherson shock strut, lower control arm, tie-rod, and wheel spindle. A coil spring mounts between the lower control arm and the body crossmember/side rail. The spindle, in addition to supporting the rear wheel, is used as an attaching location for the outer end of the control arm and the rear end of the tie-rod. The inner end of the control arm attaches to the crossmember. The forward end of the tie-rod attaches to the side rail.

Another rear strut design uses a Chapman strut that is similar to the modified MacPherson strut. The difference between the two struts is that the MacPherson strut is involved directly in the car's steering system. The Chapman strut is not. In addition, the Chapman strut can be used with conventional springs, often a leaf-type spring. It frees the Chapman strut of load-carrying duties so it can concentrate on providing exact wheel location and shock absorbing functions.

Rear leaf-spring suspension systems are used on many vehicles with conventional rear drives. These leaf springs are generally mounted longitudinally in the same manner as described earlier in this chapter for live-axle systems. A few leaf-spring systems, however, employ springs mounted transversely. Both multiple-leaf and monoleaf, or single-leaf, can be used. The transverse-leaf spring is mounted to the differential housing rather than the vehicle frame as in the longitudinal installation. The transversely mounted spring's eyes are connected to the wheel spindle assemblies.

Rear shock absorbers or shock struts have the same service limitations as those used on the front of the vehicle. They cannot be adjusted, refilled, or repaired. The procedure for inspecting rear shocks or shock struts is similar to previously mentioned front-end parts inspection. Repetition is not necessary.

Multilink Rear Suspension

A multilink rear suspension uses several control arms to guide the wheel **(Figure 46–57)**. Different models feature different types of multilink rear suspensions that satisfy the varying demands of vehicle dynamics, ride comfort, and space requirements. These include the double-wishbone rear suspension, trailing-link double-wishbone rear suspension, and trapezoidal-link rear suspension.

In the double-wishbone suspension, the wheel is guided by two triangulated lateral control arms (the

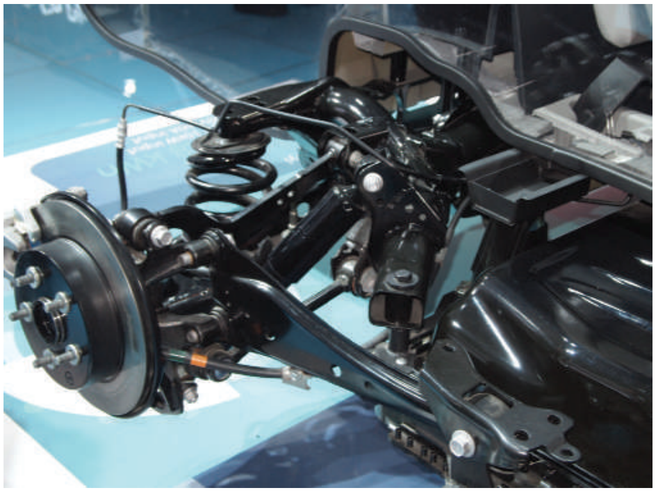

FIGURE 46–57 A multilink rear suspension.

wishbones) and a tie rod. The suspension strut is attached to the lower wishbone to provide vertical support.

The trailing-link double-wishbone suspension has a trailing link that also carries the wheel and upper and lower wishbones. The spring is located on the trailing link ahead of the center of the wheel; the shock absorber is behind it.

The trapezoidal-link rear suspension permits excellent performance, handling, and comfort. The rear wheel is fixed by an upper lateral control arm and a trapezoidal lower link with a tie rod behind it. For reduced weight, the trapezoidal link and upper control are hollow aluminum castings.

Servicing Independent Suspension Systems

Most of the servicing techniques for rear independent suspension systems—except coil, control arm, and strut removal and installation—are similar to other front- and rear-suspension parts. They have been covered earlier in this chapter. Of course, check the service information for all inspection and repair techniques of the vehicle's independent rear system.

Servicing Rear Coil Spring Raise the vehicle on a frame contact hoist or position jack stands under the frame forward of the rear-axle assembly. This allows the shock absorbers to fully extend. Place a floor jack under the center of the rear-axle housing and support the weight of the rear axle, but do not lift the vehicle off the jack stands. Disconnect the lower end of the shock absorber. Then, lower the floor jack until all of the coil-spring force is relieved. If a coil-spring positioner is used, remove it from the center of the coil spring. The coil spring can usually be removed from the vehicle at this time by lifting it from its spring seat. If the springs are to be used again, mark or tag each one so it can be returned to its original location. When a replacement is needed, always replace coil springs in pairs. This ensures equal height.

To install a spring, place the insulator on top of the coil spring and position the spring on the spring seat. The end of the top coil must be positioned to line up with the recess in the spring seat. Jack up the rear-axle housing so the spring is properly seated at the lower end and the shock absorbers line up. Reconnect the shock absorbers.

There are some definite advantages to working on one spring at a time. First of all, the assembled side of the vehicle helps support the disassembled side. It also keeps the parts aligned and eliminates the possibility of putting the parts on the wrong side of the vehicle.

Servicing Rear Struts

The biggest difference with replacing rear struts is the location of the upper mounts. In many cars, the upper strut mount may be located in the trunk, under the parcel shelf, or behind the rear seat cushion **(Figure 46–58)**. Determine how to access the upper

FIGURE 46–58 Disassembling the rear passenger area to replace the rear struts.

mount before you start in case you have to disassemble the interior of the car. Support the lower control arm with a jack and remove the lower strut connections. Once you have access to the upper mount, remove the fasteners and remove the strut from the car. Torque all fasteners once reinstalled and make sure all the interior pieces are clean.

Servicing Rear Control Arms To remove the upper rear control arms from the vehicle, remove the bolts passing through the control arms at the frame and at the axle ends. Usually the rear coil spring does not have to be removed for this. Service one side of the vehicle at a time. This simplifies realigning the parts during assembly. On a serviceable control arm, replace the control arm bushings by removing the defective bushing with an appropriate puller. Properly position the new bushing and press it into place in the same manner as is done on front suspensions. Position the repaired control arm on the vehicle and loosely install the bolts. Repeat the service on the other control arm if necessary. Properly torque the nuts and bolts once the vehicle's entire weight is on the springs again.

The coil springs must be removed to service the lower rear control arms. Again, one side of the vehicle should be serviced at a time. Once the vehicle is properly supported and the springs are dismantled, remove the nuts and bolts that pass through the control arm. Remove the control arm from the vehicle and service it in the same way as the upper control arm.

Check the service information to see if there is an adjustment for the driveline working angle. If none is specified, torque the control arm bolts to specification while the full vehicle weight is on the rear axle. This sets neutral bushing tension at normal curb height.

When there is a driveline working angle adjustment, adjust the angle before torquing the control arm bolts. After the rear suspension has been serviced, always check the working angle of the universal joints on the drive shaft. This minimizes the possibility of driveline vibration.

Some independent rear-suspension systems have ball joints that perform a function similar to the front ball joints, and they should be inspected in the same way.

Although very few cars have rear wheels that steer, some independent suspension systems have components that would normally be seen only on vehicles with four-wheel steering. Components such as tie-rod ends may appear to serve the same purpose as if they were on the front suspension. They are used to adjust the angle of the wheels for stable straight ahead performance. These suspension and steering items are covered in greater detail in Chapters 47 and 48 of this book.

Electronically Controlled Suspensions

All of the suspension systems covered up to this point are known as passive systems. Vehicle height and damping depend on fixed nonadjustable coil springs, shock absorbers, or MacPherson struts. When weight is added, the vehicle lowers as the springs are compressed. Air-adjustable shock absorbers may provide some amount of flexibility in ride height and ride firmness, but there is no way to vary this setting during operation. Passive systems can be set to provide a soft, firm, or compromise ride. Vehicle body motion and tire traction vary due to road conditions and turning and braking forces. Passive systems have no way of adjusting to these changes.

Advances in electronic sensor and computer control technology have led to a new generation of suspension systems. The simplest systems are level control systems that use electronic height sensors to control an air compressor linked to air-adjustable shock absorbers.

More advanced adaptive suspensions are capable of altering shock damping and ride height continuously. Electronic sensors **(Figure 46–59)** provide input data to a computer. The computer adjusts air spring and shock damping settings to match road and driving conditions.

The most advanced computer-controlled suspension systems are true active suspensions. Some use forward-looking cameras to scan the road ahead and adjust the suspension before hitting bumps and dips in the road. These systems are usually hydraulically, rather than air, controlled. They use high-pressure hydraulic actuators to carry the vehicle's weight rather than conventional springs or air springs. However, some systems, such as AIRMATIC from Mercedes-Benz, use electronically controlled air springs to carry weight and control ride quality.

The unique feature of an active suspension is that it can be programed to respond almost perfectly to various operating conditions. For example, some late-model Ford Fusions have a unique computer-controlled shock absorber system that provides continuously controlled damping. In effect, the system softens the blow when a tire falls into a pothole on the road. It detects the pothole and then stops the tire from dropping all the way into it, which means the tires won't strike the opposite side of the pothole as harshly. This reduces the jarring felt by the vehicle's passengers.

The system uses 12 sensors and active dampers that can adjust the shock absorbers every

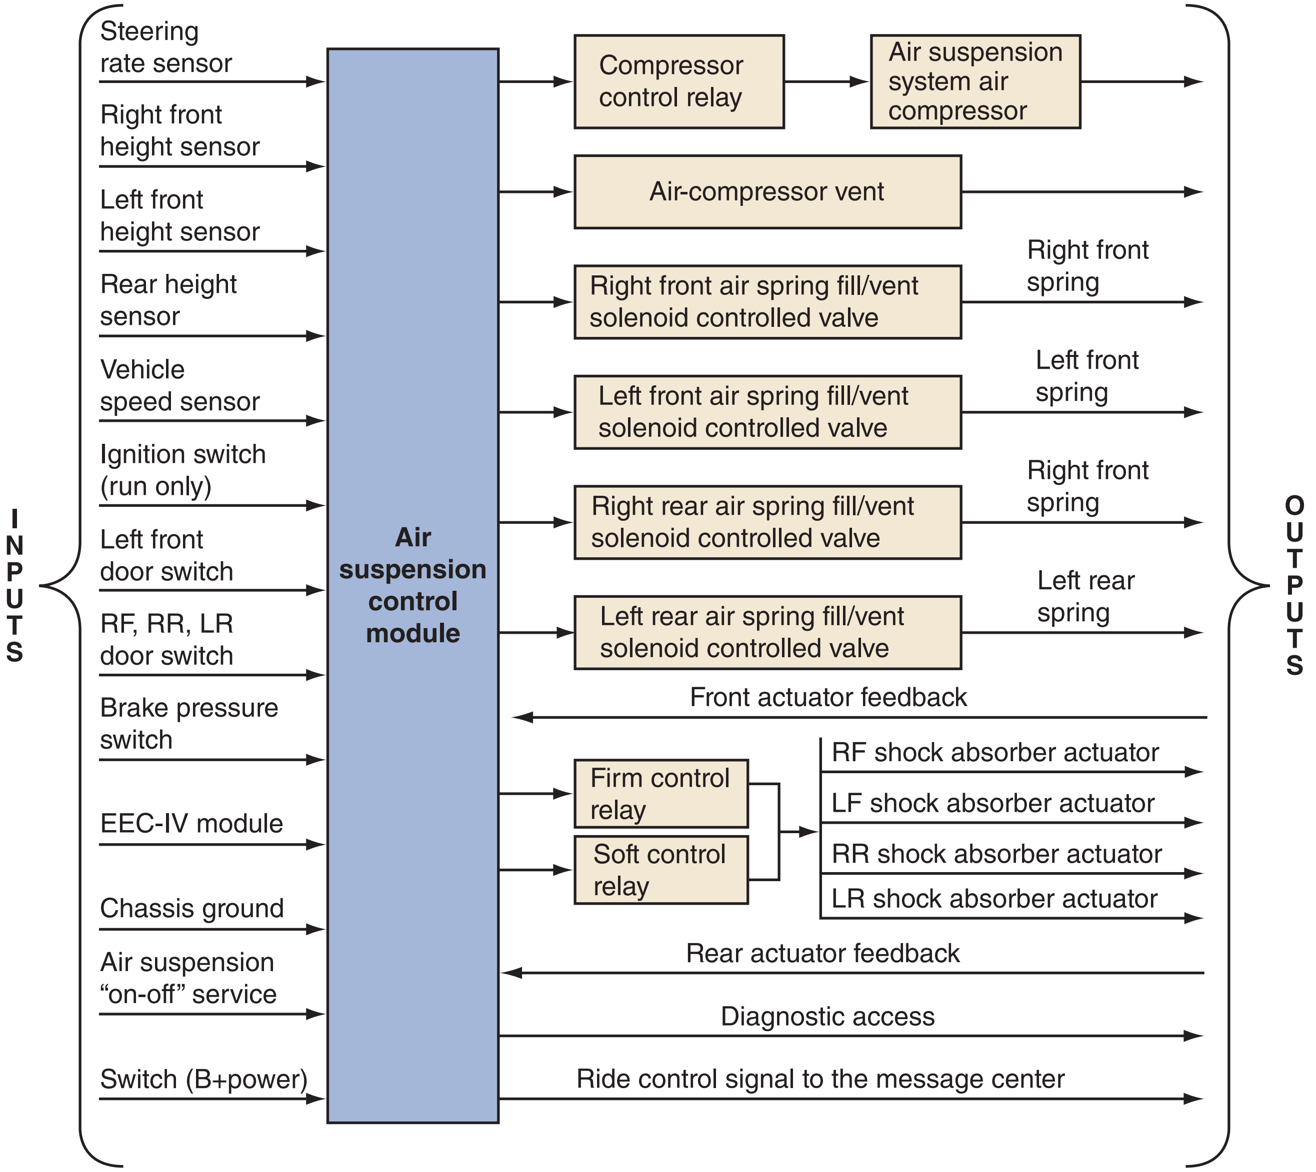

FIGURE 46–59 The various inputs and outputs for an electronic suspension system.

2 milliseconds. The rear suspension can respond faster; signals from the front wheel provide warning signals for the rear wheel before it reaches the pothole. The system can also be used in Sport mode to improve handling and cornering.

Active systems using hydraulic actuators are presently used on a limited number of high-performance vehicles. Most manufacturers are introducing various adaptive suspension systems that rely on pneumatically actuated air springs and dampers.

Some late-model pickups and SUVs offer air suspension systems. These systems are added to existing leaf-spring suspensions. The air spring is positioned between the center of the leaf spring and the frame of the truck. The air spring serves as an adjustable and additional spring at each end of the axle.

Adaptive Suspensions

Adaptive suspensions use electronic shock absorbers with variable valving. In some cases, variable air spring rates are used to adapt the vehicle's ride characteristics to the prevailing road conditions or driver demands.

Electronic sensors monitor factors such as vehicle height, vehicle speed, steering angle, braking force, door position, shock damping status, engine vacuum, throttle position, and ignition switching. A computer is used to analyze this input and switch the suspension into a preset operating mode that matches existing conditions. Some systems are fully automatic. Others allow the driver to select the ride mode.

At present, adaptive suspensions are less costly and complicated than hydraulically controlled active suspensions. However, they do have some limitations. Although they can reduce body roll, adaptive suspensions cannot eliminate it like true active systems. Adaptive systems also experience a slight delay in their reaction time, although some systems can change shock valving in as little as 150 microseconds.

System Components There are many different designs and components used by the manufacturers to accomplish the same task. Some systems use adjustable shocks, while others use air springs at each side of the axles. The air spring membrane is similar to a tire in construction. A solenoid valve and filter assembly allows clean air to be added or released from the air spring. Adding or removing air changes the ride height of the vehicle.

The airflow to the springs is controlled by the interaction of the air compressor, system sensors, computer control module, and solenoid valves. All of the air-operated parts of the system are connected by nylon tubing.

Compressor. The compressor supplies the air pressure for operating the entire system. It is often a positive displacement single piston pump powered by a 12-volt DC motor. A regenerative air dryer is attached to the compressor output to remove moisture from the air before it is delivered to the air springs. The compressor is operated through the use of an electric relay controlled by the computer module.

Sensors. Vehicle height sensors can be rotary Hall-effect sensors that enable the computer to more accurately measure ride height as well as to compensate for road variations **(Figure 46–60)**. This prevents the vehicle from bottoming out when crossing over railroad tracks or similar road irregularities.

FIGURE 46–60 A sensor used for ride and stability control systems.

Advanced systems also read the steering angle by using a photo diode and shutter location inside the steering column. This allows the system to firm up the suspension when the vehicle is turning. The system also reads engine vacuum or throttle position to stiffen the suspension when the vehicle is accelerating. A brake sensor allows the system to compensate for front nosedive during hard braking. Some systems use a special G-sensor to sense sudden acceleration or braking. Other adaptive systems use a yaw sensor to pick up body roll when cornering.

Electronic Shock Absorbers. Many adaptive suspension systems use electronically controlled shock absorbers that feature variable shock damping. The degree of damping is controlled by the computer based on input from the vehicle speed, steering angle, and braking sensors. As explained earlier in this chapter, variable shock damping is accomplished by varying the size of the metering orifices inside the shock. A small actuating motor mounted on top of the shock absorber rotates a control rod that alters the size of the metering orifices.

A recent advancement in adaptive suspension technology is the use of real-time shock damping. These systems use solenoid-actuated shocks rather than the motor driven shocks. Solenoids allow almost instantaneous valving changes. This means the suspension can react to bumps and body motions as they happen. Real-time adaptive systems deliver most of the handling advantages of a full active suspension without increased vehicle weight and power drain. With these systems, changes to shock valving in as little as 10 milliseconds are possible when bumps are encountered.

Electronic Struts. Some systems use an electronically controlled strut in place of the air spring and shock absorber **(Figure 46–61)**. Design and operation is similar to electronic shock absorbers. A valve selector or variable orifice located inside the strut controls fluid pressure in the suspension system based on input from many sensors and commands from the system's control module.

Some variable damping suspension systems use air or gas rather than a fluid. At speeds up to 40 mph (65 km/h), the orifice is fully open and provides full flow. From 40 to 60 mph (65 to 100 km/h), the orifice is in the normal position and flow is restricted. At speeds more than 60 mph (100 km/h), or when the vehicle is accelerating or braking, the variable orifice is shifted to the firm position.

The use of a variable orifice in the damper control, coupled with the deflected disc valving, provides optimum fluid flow control for both rebound and jounce strokes. In the comfort mode, the selector is

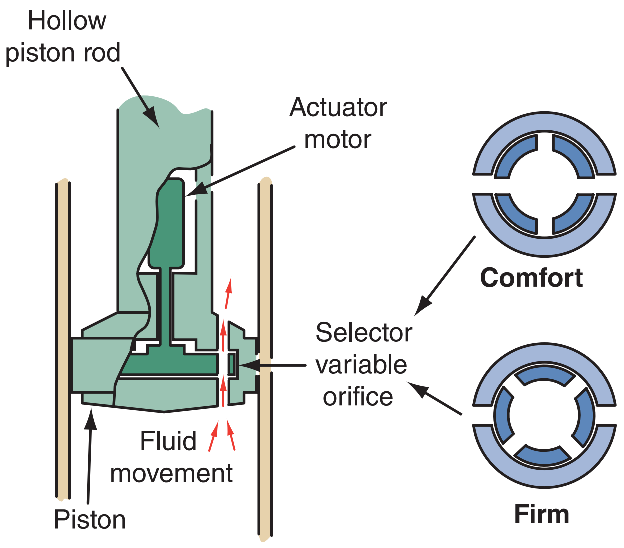

FIGURE 46-61 Computer command ride strut. Four electronically controlled struts are used on many adaptive suspension systems. Based on input from the computer, the valving selector shifts the variable by-pass orifice to a comfort, normal, or firm setting.

set to allow fluid flow primarily through the large selector orifice to achieve minimum damping forces. While in the normal mode, the unit is set to balance fluid flows between the small selector orifice and the deflected disc valving to provide moderate damping forces. Under conditions in which the firm mode is needed, the selector is rotated to its firm or blocked position and fluid flows entirely through the deflected disc valving.

The damper control also can raise or lower the vehicle's height. This action also improves the car's aerodynamic characteristics at highway speed. As speed increases, the suspension reduces the vehicle's height and the front end angles downward. This action tends to reduce wind resistance for greater stability and better gas mileage. As the vehicle slows, the suspension brings the body up to its normal height and level position.

Computer Control Module. An electronic module controls the air compressor motor (through a relay), the compressor vent solenoid, and the four air spring solenoids. The computer module also controls operation of electronic shock absorber actuating motors and electronic strut valving selectors. The control module receives input from all system sensors.

The computer module also has the capability of performing diagnostic tests on the system. It has a preprogrammed routine for properly fitting air springs after servicing. The module also controls the dash-mounted system warning light.

Electrical power to operate the basic air suspension system is distributed by the main body wiring harness. Each wiring harness involved has a special function in the typical air suspension system.

Warning! The compressor relay, compressor vent solenoid, and all air spring solenoids have internal diodes for electrical noise suppression and are polarity sensitive. Care must be taken when servicing these so as not to switch the battery feed and ground circuits, or component damage will result. When charging the battery, the ignition switch must be in the off position if the air suspension switch is on, or damage to the air compressor relay or motor may occur. However, use of a battery charger while performing the diagnostic test or air spring fill option is acceptable. Set it to a rate to maintain but not damage the vehicle battery.

Electronic Leveling Control. Adaptive suspension systems are capable of adjusting the suspension system during operation. Less complicated electronic level-control systems are used on many large and mid-size vehicles.

These systems do not use a computer module. In most cases, height sensors are the only types of sensors used. These height sensors sense when passenger weight or cargo is added to or removed from the vehicle **(Figure 46–62)**. The height sensors control two basic circuits. The compressor relay coil grounds circuits that activate the compressor. The exhaust solenoid coil grounds circuits that vent air from the system.

To prevent falsely actuating the compressor relay or exhaust solenoid circuits during normal ride motions, the sensor circuitry provides an 8- to 15-second delay before either circuit can be completed.

In addition, the typical sensor electronically limits compressor run time or exhaust solenoid energized time to a maximum of approximately 3½ minutes. This time limit function is necessary to prevent continuous compressor operation in a case of a solenoid malfunction. Turning the ignition off and on resets the electronic timer circuit to renew the

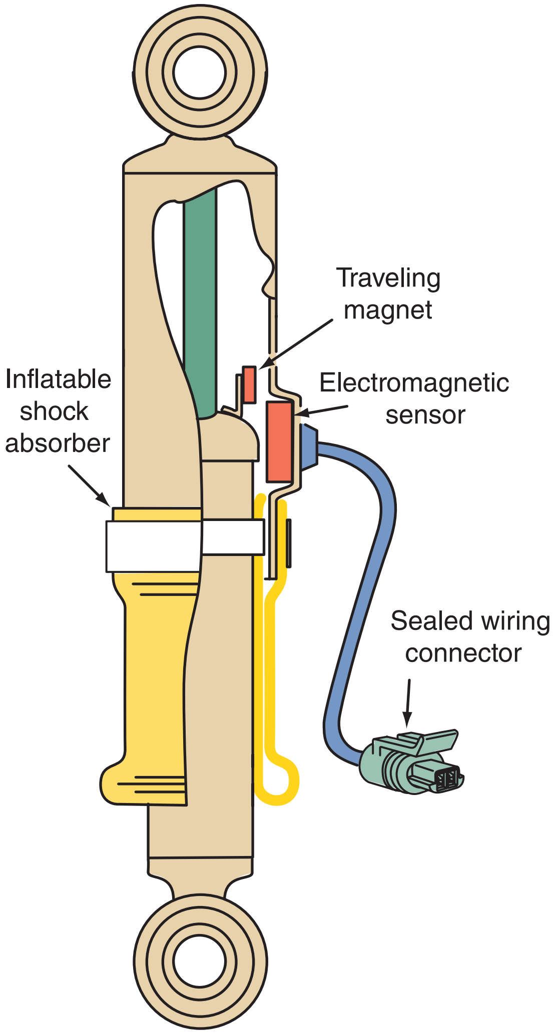

FIGURE 46–62 A load-sensing shock absorber.

3½-minute maximum run time. The height sensor is mounted to the frame crossmember in the rear. The sensor actuator arm is attached to the rear upper control arm by a link. The link should be attached to the metal arm when making any trim adjustment.

When the air line is attached to the shock absorber fittings or compressor dryer fitting, the retainer clip snaps into a groove in the fitting, locking the air line in position. To remove the air line, spread the retainer clip, release it from the groove, and pull on the air line.

Adjustable Pneumatic Suspension Adjustable pneumatic suspension at the front and rear wheels is a feature on some AWD vehicles. By varying the vehicle's ground clearance, it can be used off-road but also performs and handles well on the highway. There are four ride-height positions that can be selected either manually or automatically, with a total range of over 8 inches (203 mm) of ground clearance. At highway speeds, the vehicle's ground clearance is 5.6 inches (142 mm). Urban mode raises it a full inch. For moderate off-road and local driving, ground clearance is 7.6 inches (193 mm). For severe off-road conditions at speeds under 25 mph (40 km/h), maximum clearance is 8.2 inches (208 mm). The vehicle will adjust to the desired height based on vehicle speed, or the driver can temporarily override the setting by depressing a button.

MagneRide

MagneRide is a semiactive suspension system, which features shocks or struts with no electromechanical valves or small moving parts. Instead of valve-controlled orifices, MagneRide regulates the flow of fluid by a variable magnetic field produced by a small electric coil mounted in the shock **(Figure 46–63)**. The shocks are filled with magneto-rheological (MR) fluid. MR fluid consists of magnetically soft particles, such as iron, suspended in synthetic hydrocarbon fluid.

The action of the shock forces the MR fluid through a magnetized opening in each shock. When the shock is in its off state, the fluid is not magnetized and flows freely through the orifice. When current is sent to the coil, the fluid becomes magnetized and its viscosity changes instantly **(Figure 46–64)**.

FIGURE 46–63 A magneto-rheological fluid-based strut.

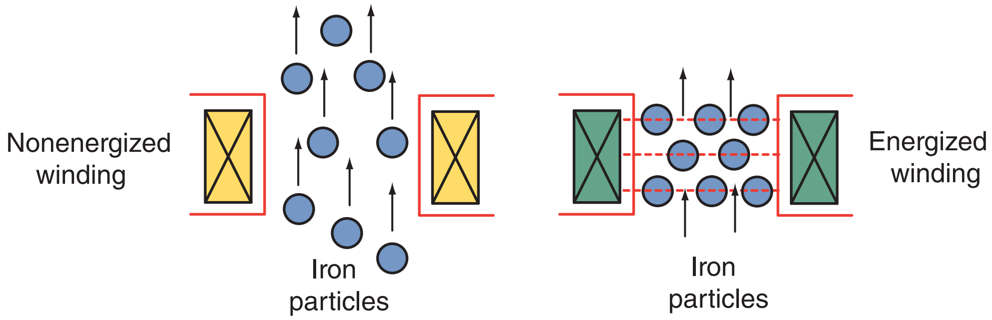

FIGURE 46-64 The iron particles in the MR fluid align themselves when they pass through the magnetic field, causing the fluid to stiffen.

The material changes from a fluid state to a semisolid state that is directly proportional to the magnetic field applied to it. With little or no electrical current, the iron particles are randomly distributed, and the fluid passes freely through the piston orifice. When a strong electrical current is applied to the coil, the resulting magnetic field aligns the iron particles so that the fluid stiffens and the flow is resisted. This condition causes heavy damping. The resulting damping force is proportional to the viscosity, which is proportional to the strength of the magnetic field.

Sensors monitoring wheel position, lateral acceleration, vehicle speed, steering wheel angle, and brake pedal angle are inputs to the control module that sends current to the coil in the shocks. This system provides extremely quick response time, typically about 5 ms, and the fluid is capable of reacting 30,000 times per second.

Servicing Electronic Suspension Components

Most electronic suspension servicing requires the removal and replacement of a component. The correct procedures for doing this are given in the manufacturer's service information. Serviceable items include the air compressor, mounting brackets, height sensors, air springs, air lines and connections, gas struts, strut mounts, control arm components, shock absorbers, and stabilizer bars.

Attention to fasteners is extremely important when serving all suspension systems, especially electronic systems. Failure to adhere to the advice given about fasteners can result in a sudden failure of the air spring or suspension system. Suspension fasteners can affect performance of vital components and systems or could result in additional service expenses. All fasteners must be replaced with fasteners of the same part number or with an equivalent part. Never use a replacement part of lesser quality or substitute design. All fasteners must be tightened to the specified torque. New fasteners must be installed whenever the originals are loosened or removed and when new components are installed.

Diagnosis

A scan tool and/or a special electronic tester is used to diagnose most electronic suspension systems. These can only retrieve DTCs; they may also be able to activate various actuators in the system. The exact procedures and available data from the vehicle's computer will vary with manufacturer and the system found on the vehicle. Always refer to the correct service information when diagnosing electronic systems.

Diagnosis should begin with gathering as much information as possible from the customer. Make sure you know exactly what the concern is and the conditions at the time the malfunction occurred. Verify the customer's concern by attempting to duplicate the conditions during a road test.

Check the voltage at the battery. If the voltage is below 11 volts, recharge or replace the battery before continuing with diagnostics. Check the fuses, connectors, and wiring harnesses for the suspension system and repair them as necessary. Start the engine and allow it to warm up. Then connect the scan tool or tester. Retrieve all DTCs from the system. If the scan tool or tester is unable to communicate with the vehicle's computer, diagnose the cause of this before proceeding.

GO TO Chapter 22 for the procedures for retrieving DTCs and CAN communication problem diagnostic procedures.

Check the DTC charts to see if the DTCs match the symptoms exhibited by the vehicle. If they do, proceed

to follow the troubleshooting chart related to each DTC. If the DTCs do not match the symptoms, clear them and recheck for trouble codes after your diagnosis of the suspension system has been completed.

If there are no DTCs related to the problem, record the PIDs and compare them to specifications **(Figure 46–65)**. If the cause of the problem is still not evident, refer to the symptoms chart provided by the manufacturer. Check those areas identified as possible causes of the problem. If the tester has the capability of activating the system's actuators, do this now. In many cases, the tester can cause action at one wheel at a time. The suspension of one wheel can be manually energized and the vehicle will tilt. The actuator can then be de-energized and the vehicle will return to its original position. This procedure should

be completed at each wheel. If the suspension does not respond correctly to these commands, the corner of the suspension that did not should be thoroughly checked. If all corners responded as they should, the problem is most likely not caused by something in the electronic system, and diagnosis should continue with checks of the conventional suspension parts.

Once the cause is identified, it should be replaced or repaired; then the repair ought to be confirmed. Drive the vehicle under the same conditions during which the concern was present. Also recheck the system for any new DTCs.

Warning! NEVER remove an air spring when there is pressure in the air spring. Do not remove any components supporting an air spring without either exhausting the air or providing support for the air spring. When servicing any air suspension component, power to the air system must be shut off by turning the air suspension switch (in the luggage compartment) off or by disconnecting the battery. Most air suspension systems are equipped with a warning light. The light comes on if there is a problem, or when servicing the system.

Vehicle Alignment

Aligning a vehicle with an electronic suspension system is essentially the same as the aligning procedure described in Chapter 48, with one notable exception—curb height.

Curb height is an important dimension because it affects the other alignment angles. Caster is the most obvious one that is affected, but front camber and toe can also be included. Curb height is especially critical when checking rear camber and toe on independent rear suspensions. With electronic suspension, the ride can vary depending on various circumstances. The only way to guarantee the suspension is at the correct curb height is to preset it. Setting the vehicle up properly to check and set the alignment often requires following the manufacturers' service information exactly and using a scan tool to put the system into service mode. Do not attempt to check or set wheel alignment on a vehicle with an active suspension unless you have the right information and equipment.

Active Suspensions

Some of the advanced adaptive suspension systems may be called **active suspensions**. In this text, active suspensions refer to those controlled by double-acting hydraulic cylinders or solenoids (usually called actuators) that are mounted at each wheel.

CUSTOMER CARE

Because the technician is seldom present when a vehicle requires towing, it is important to advise the customer of the proper procedures so the tow operator does not damage the electronic suspension system. You must also know the proper hoist lifting and jacking restrictions.

When towing, it must be remembered that when the ignition is off, the automatic leveling suspension is still on. Before lifting the vehicle, be sure the ignition switch is turned off and the trunk switch deactivated. When towed from the front, towing should not exceed a speed of 35 mph (60 km/h) or a distance of 50 miles (80 km/h). When the car is towed from the rear, speeds should not exceed 50 mph (80 km/h) (or 35 mph [60 km/h] on bumpy pavement).

A body hoist is usually the only type of lift recommended. Most manufacturers warn against using a suspension hoist. The proper sequence is to position the car over the lift, shut off the ignition, and then deactivate the system.

If a body hoist is not available, a floor jack and jack stands will do. Lift the car by the front cross-member and the rear jacking points that are just in front of the rear wheel wells. Jack stands should be used to support the car.

In all situations, the lifting theory is the same. The suspension should be free to hang down while the car is in the air. This allows the wheels to be supported by the struts in the front and the shocks at the rear, both in their full extension (rebound) positions. Thus, the membrane of each air spring retains its proper shape while the car is in the air.

Each actuator maintains a sort of hydraulic equilibrium with the others to carry the vehicle's weight, while maintaining the desired body attitude. At the same time, each actuator serves as its own shock absorber, eliminating the need for yet another traditional suspension component.

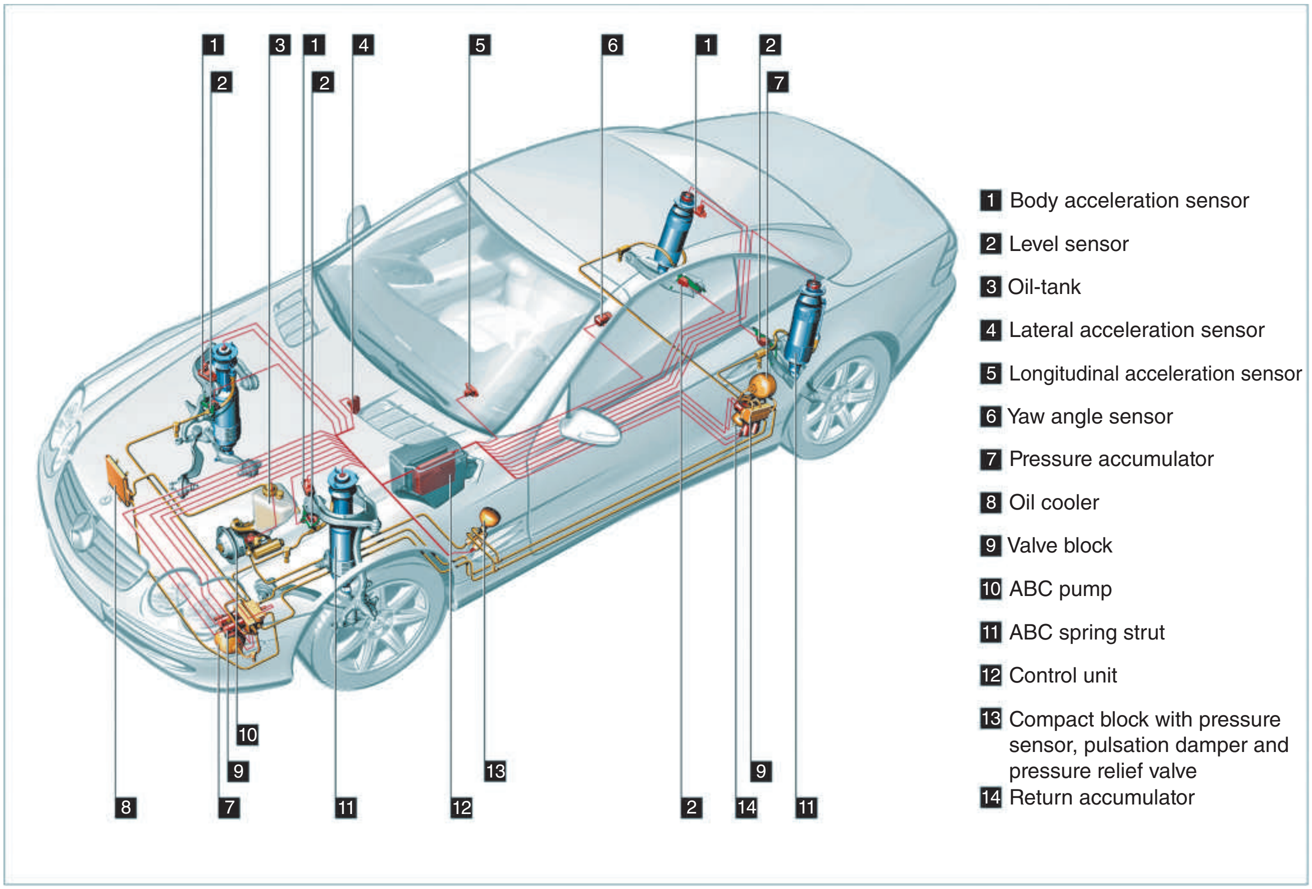
In other words, each hydraulic actuator acts as both a spring (with variable-rate damping characteristics) and a variable-rate shock absorber. This is accomplished in an active suspension system by varying the hydraulic pressure within each cylinder and the rate at which it increases or decreases. By bleeding or adding hydraulic pressure from the individual actuators, each wheel can react independently to changing road conditions.

The components that make such a system possible are the actuator control valves, various sensors, and the chassis computer **(Figure 46–66)**. Feeding information to a computer are a number of specialized sensors. Each actuator has a linear displacement sensor and an acceleration sensor to keep the computer informed about the actuator's relative position. This enables the computer to track the extension and compression of each actuator, and to know when each wheel is undergoing jounce or rebound. There are also load sensors and hub acceleration sensors in each wheel to measure how heavily each wheel is loaded.

A steering angle sensor is used to signal the computer when the vehicle is turning. To monitor body motions, a roll sensor and lateral acceleration and G-sensors are used. The computer also monitors hydraulic pressure within the system and the speed of the pump monitor.

Once it has all the necessary inputs, the computer can then regulate the flow of hydraulic pressure within each individual actuator according to any number of variables and its own built-in program. Another nice feature of a suspension such as this is that it can be programmed to behave in a variety of unique and currently impossible ways: leaning or rolling into turns, for example, or even raising a flat tire on command in order to change the tire without using a separate jack.

When the wheel of an active suspension hits a bump, the sensors detect the sudden upward deflection of the wheel. The computer recognizes the change as a bump, and instantly opens a control valve to bleed pressure from the hydraulic actuator. The rate at which pressure is bled from the actuator



Chrysler LLC.

FIGURE 46–66 An active suspension system.

determines the cushioning of the bump and the relative harshness or softness of the ride. The rate can be varied at any point during jounce or rebound to produce a variable spring rate effect. In other words, the feel of the suspension can be programmed to respond in an almost indefinite variety of ways. Once the bump has been absorbed by the actuator, pressure is forced back into it to keep the wheel in contact with the road and to maintain the suspension's desired ride height.

During hard braking with a conventional suspension system, there is a tendency for a vehicle to make a dive. The weight of the vehicle seemingly pushes the front of the car downward and the back upward. During hard braking, the active suspension increases air pressure in the front actuators and reduces air pressure in the rear actuators. These actions minimize dive to keep the vehicle level and make it easier for the driver to control. After braking, valves operate to equalize air pressures in front and rear air actuators and level the vehicle again.

Frequently, when a driver depresses the accelerator quickly during hard acceleration, the front end of the vehicle tends to lift up, while the rear end lowers. The action is known as squat. With an active suspension system, squat is controlled by the operating valve's solenoids, which increase the air pressure in rear wheel actuators and reduce air pressure in front wheel actuators. When the vehicle is no longer accelerating quickly, the control system operates valves to equalize air pressures and level the vehicle. Thus, an active suspension changes the height of the front, rear, or either side of the vehicle to counteract tilting, rolling, and leaning. These active attitude control functions improve vehicle stability and increase tire traction and driver control.

The power required for a totally active system is only 3 to 5 horsepower (about the same as a typical power steering pump). Power consumption is lowest when the system is least active, as when driving on a smooth road. Rough roads and hard maneuvers, on the other hand, put more of a demand on the system. The hydraulic pump works harder and thus requires more power.

Power consumption can be reduced by going with a semiactive suspension that uses small springs with the hydraulic actuators. The springs help to support the vehicle's weight, which reduces the load on the actuators. Smaller actuators that require less hydraulic power can then be used, which reduces the bulk and weight of the system. The addition of springs also adds a certain margin of safety to the system to keep it from going flat should the hydraulics spring a leak.

Although not as widely used as electronic leveling or adaptive suspension systems, hydraulic active suspensions are sure to become more common.

SUMMARY

- Four types of springs are used in suspension systems: coil, leaf, torsion bar, and air.
- Springs take care of two fundamental wheel actions: jounce and rebound.
- Common coil-spring materials include carbon steel, carbon boron, steel, and alloy steels. Alloy steels, such as those containing chromium and silicon, improve the coil's resistance to relaxation.
- Two basic designs of coil springs are used in vehicles: linear rate and variable rate.
- Leaf springs are made of steel or a fiber composite.
- In torsion suspension, the bar may run either from front to rear or side to side across the chassis.
- Air springs are generally only used in computer-controlled suspension systems.
- Shock absorbers damp or control motion in a vehicle. A conventional shock absorber is a velocity-sensitive hydraulic damping device. The faster it moves, the more resistance it has to the movement.
- Shock absorbers can be mounted either vertically or at an angle. Angle mounting of shock absorbers improves vehicle stability and dampens accelerating and braking torque.
- There are two basic adjustable air shock systems: the manual fill type and the automatic or electronic load-leveling type.
- MacPherson struts provide the damping function of a shock absorber. In addition, they serve to locate the spring and to fix the position of the suspension.
- Domestic struts have taken two forms: a concentric coil spring around the strut itself and a spring located between the lower control arm and the frame.
- Independent front suspension (IFS) must keep the wheels rigidly positioned and at the same time allow them to steer right and left. In addition, because of weight transfer during braking, the front-suspension system absorbs most of the braking torque. When accomplishing this, it must provide good ride and stability characteristics.
- The unequal length arm or short-long arm (SLA) suspension system is most commonly used on domestic vehicles.
- Live-axle is the traditional rear-suspension system and consists of springs used in conjunction with a live-axle (one in which the differential axle, wheel bearings, and brakes act as a unit). The springs are either of leaf or coil type.
- Semi-independent suspension is used on many front-wheel-drive models.
- Three strut designs are frequently used in IFS systems: the conventional MacPherson strut, the modified MacPherson strut, and the Chapman strut.
- The two basic types of computer suspension systems are adaptive and active.
- Electronically controlled suspensions can be either simple load-leveling systems, adaptive systems, or fully active systems. Adaptive and systems are computer controlled.
- Adaptive suspensions can alter vehicle ride height and shock absorber damping while the vehicle is in motion. Such systems use air springs and electronic shock absorbers or struts.
- Active suspensions are hydraulically operated actuators to control up-and-down and side-to-side movement. They can be programmed to respond to certain road conditions and turning forces.

CHAPTER 47

STEERING SYSTEMS

The purpose of the steering system seems simple—turn the front wheels. However, as vehicles have changed through the years, so have the requirements of the steering system. In addition to turning the front wheels, and in some cases also the rear wheels, the steering system is now integrated with driver assistance technology such as self-parking, lane departure control, and semiautonomous operation. Until recently, few cars had stability control systems or electric steering assist; today all new vehicles have some type of stability control and most vehicles have electrically assisted steering **(Figure 47–1)**. Until vehicles have purely electronic steering, mechanical steering components will still be the foundation of the steering system.

Mechanical Steering Systems

The steering system is composed of three major subsystems: the steering linkage, steering gear, and steering column and wheel. As the steering wheel is turned by the driver, the steering gear transfers this motion to the steering linkage. The steering linkage turns the wheels to control the vehicle's direction. Although there are many variations to this system, these three major assemblies are in all steering systems.

Steering Linkage

The term steering linkage is applied to the system of pivots and connecting parts placed between the steering gear and the steering arms that are attached to the front or rear wheels that control the direction of vehicle travel. The steering linkage transfers the motion of the steering gear output shaft to the steering arms, turning the wheels to maneuver the vehicle. The steering arms are the part of the steering knuckle that curve in toward the center of the vehicle and connect to the steering linkage.

The type of front-wheel suspension (independent wheel suspension as compared with a solid front axle) greatly influences steering geometry. Most passenger cars, light trucks, and recreational vehicles have independent front-wheel suspension systems. Therefore, a steering linkage arrangement that tolerates relatively large wheel movement must be used.

Parallelogram Steering Linkage

A parallelogram type of steering linkage arrangement was at one time the most common type used on passenger cars. It is used with the short-long arm suspension and a recirculating ball steering gearbox. Parallelogram steering linkage can be placed behind the front-wheel suspension **(Figure 47–2A)** or ahead of the front-wheel suspension **(Figure 47–2B)**. The components in a parallelogram steering linkage arrangement are the Pitman arm, idler arm, links, and tie-rods.

Pitman Arm The **Pitman arm (Figure 47–3)** connects the linkage to the steering gear located at the base of the column. It transmits motion from the gear to the linkage, causing the linkage to move left or right to turn the wheels in the appropriate direction. It also serves to maintain the height of the center link. This ensures that the tie-rods are able to be parallel to the control arm movement and avoid unsteady toe settings or **bump steer**. *Toe*, a critical alignment factor, is a term that defines how well the tires point to the direction of the vehicle.

Idler Arm The **idler arm** or idler arm assembly **(Figure 47–4)** is normally attached, on the opposite side of the center link, from the Pitman arm and to the car frame, supporting the center link at the correct height. A pivot built into the arm or assembly permits sideways movement of the linkage. On some linkages, such as those on a few light-duty trucks, two idler arms are used.

Links Links, depending on the design application, can be referred to as **center links**, drag or steering links **(Figure 47–5)**. Their purpose is to control sideways linkage movement, which changes the wheel's direction. Because they usually are also mounting locations for tie-rods, they are very important for maintaining correct toe settings. If they are not mounted at the correct height, toe is unstable and a condition known as the toe change or bump steer is produced. Center links and drag links can be used either alone or in conjunction with each other, depending on the particular steering design. On some vehicles, a steering damper may be attached to the center link and to

SHOP TALK

A linkage component can be a wear or nonwear component. If the part has a ball joint socket, it is considered a wear component. If the part only has a bore for the ball joint stud of another component to connect it to, it is considered a nonwear part. If a center link is nonwear, the Pitman arm is normally a wear arm. If the link is wear, the Pitman arm is usually nonwear. Idler arm assemblies are always subject to wear.

the frame. The damper reduces the effects of road induced vibrations on the steering wheel.

Tie-Rods **Tie-rods** and tie-rod assemblies make the final connections between the steering linkage and steering knuckles. In a parallelogram steering linkage, the tie-rods have ball socket assemblies at each end. One end is attached to the steering arm and the other end to the center link. Tie-rod assemblies consist of inner tie-rod ends, which are connected to the opposite sides of the center link; outer tie-rod ends, which connect to the steering knuckles; and adjusting sleeves or bolts, which join the inner and outer tie-rod ends, permitting the tie-rod length to be adjusted for correct toe settings **(Figure 47–6)**.

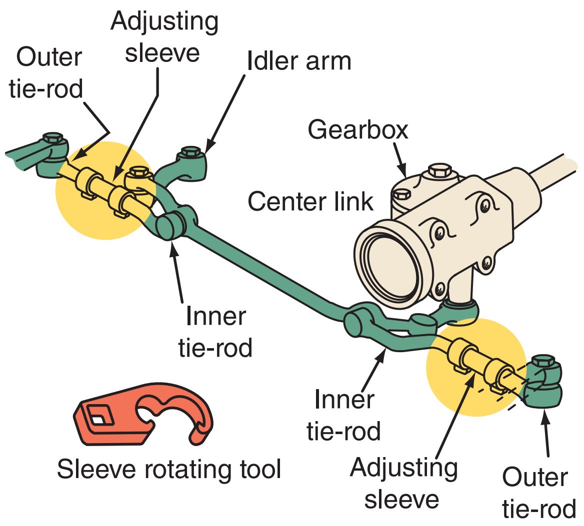

FIGURE 47-6 A tie-rod assembly.

Cross Steer and Haltenberger Linkages

Vehicles with solid front axles, front live axles, or twin I-beam suspensions typically use either a cross steer or Haltenberger linkage **(Figure 47–7)**. These linkage arrangements use long tie-rods, often called drag links, and a Pitman arm, instead of parallelogram linkage. These linkages allow for the movement of the front suspension without causing bump steer.

Steering Damper

The purpose of a steering damper is simply to reduce the amount of road shock that is transmitted up through the steering column. Steering dampers are found mostly on 4WD, especially those fitted with large tires. The damper serves the same function as a shock absorber but is mounted horizontally to the steering linkage—one end to the center link and the other to the frame.

Rack and Pinion Steering Linkage A **rack and pinion** is lighter in weight and has fewer components than parallelogram steering **(Figure 47–8)**. Tie rods are used in the same fashion on both systems, but the resemblance stops there. Steering input is received from a pinion gear attached to the steering column. This gear moves a toothed rack that is attached to the tie-rods.

In the rack and pinion steering arrangement, there is no Pitman arm, idler arm assembly, or center link. The rack performs the task of the center link. Its movement pushes and pulls the tie-rods to change the wheel's direction. The tie-rods are the only steering linkage parts used in a rack and pinion system.

Most rack and pinion assemblies **(Figure 47–9)** are composed of a tube in which the steering rack can slide. The rack is a rod with gear teeth cut along its length. The inner tie-rods attach either to the ends of the rack gear or bolt to its center. When the tie-rods thread onto the ends of the rack gear it is called an end take-off rack. When the tie-rods bolt to the center of the rack gear it is called a center take-off rack.

The rack meshes with the teeth of a small pinion gear. The pinion gear is at the end of the steering column. The two inner tie-rod ends, which are attached to the rack gear, are covered by rubber bellows boots that protect the rack from contamination. The inner tie-rods connect to outer tie-rod ends, which connect to the steering arms. The rack and pinion housing is fastened to the vehicle at two or three points. Typically, the rack is mounted on rubber bushings. Like the parallelogram linkage, it can be mounted in front of or behind the suspension.

In some cases, the rack and pinion steering gear on unibody cars is bolted directly to a body panel, like a cowl. This is common with center take-off racks **(Figure 47–10)**. When this is done, the body

FIGURE 47-7 A cross link system on a 4WD truck.

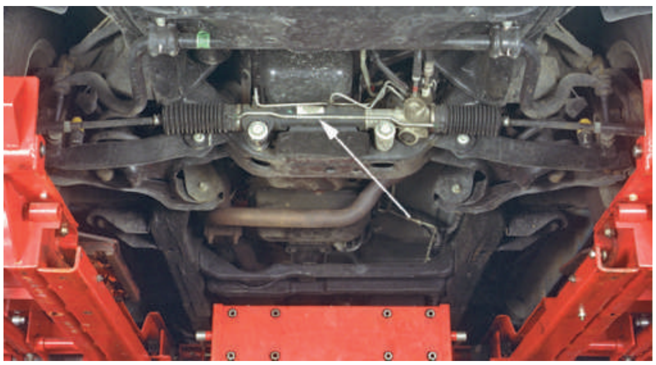

FIGURE 47-8 A rack and pinion steering system.

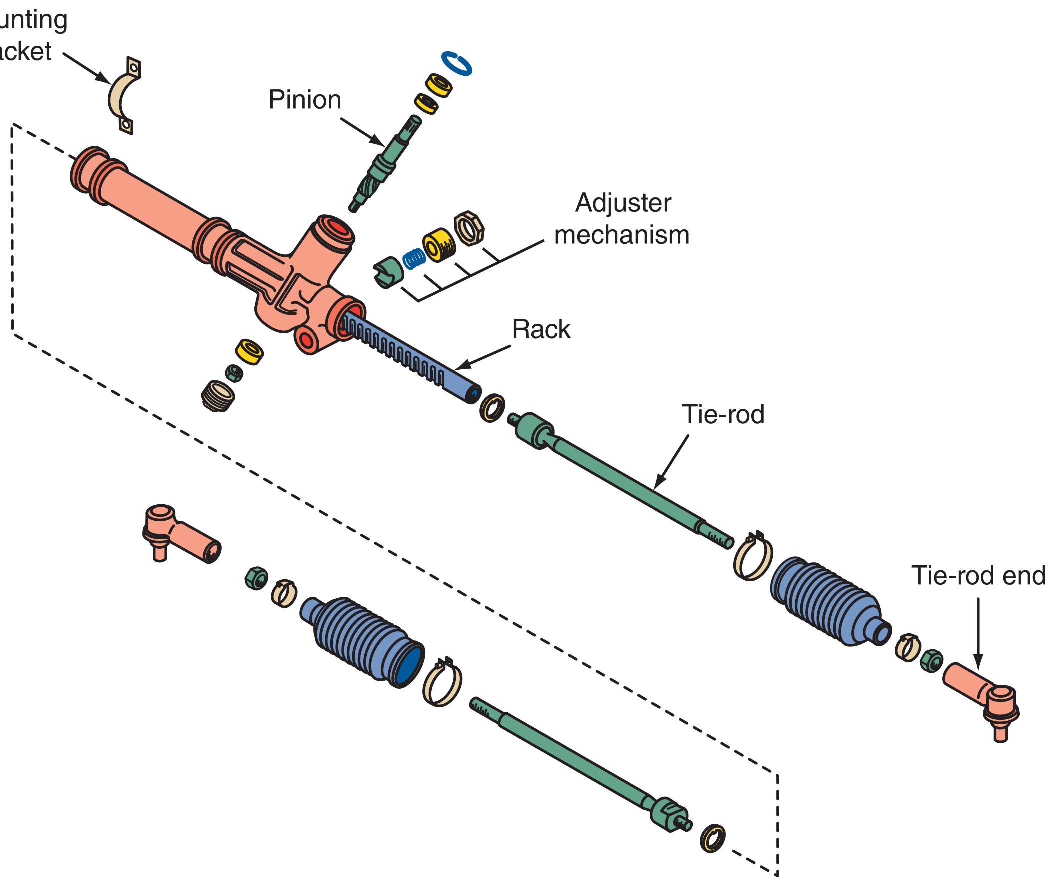

FIGURE 47–9 A disassembled view of a manual rack and pinion steering gear.

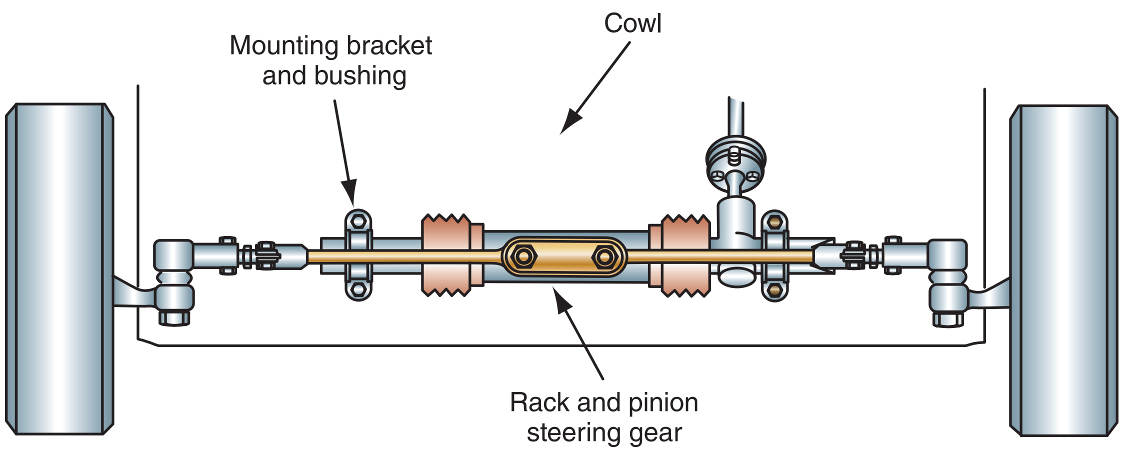

FIGURE 47–10 A center take-off rack and pinion.

panel must hold the steering gear in its correct location. The unibody structure must maintain the proper relationship of the steering and suspension parts to each other. Along with other advantages, the rack and pinion steering system combined with the MacPherson strut suspension system is found in most front-wheel-drive unibody vehicles because of their weight- and space-saving feature.

The driver gets a greater feeling of the road with rack and pinion because there are fewer friction points. Fewer friction points can also reduce the system's total ability to isolate and dampen vibrations.

Rack The rack is a toothed bar contained in a metal housing. The rack maintains the correct height of the

steering components so that the tie-rod movement is able to parallel control arm movement.

The rack is similar to the parallelogram center link in that its sideways movement in the housing is what pulls or pushes the tie-rods to change wheel directions.

Pinion The pinion is a toothed or worm gear moved by the steering wheel. The pinion gear meshes with the teeth in the rack so that the rack is propelled sideways in response to the turning of the pinion.

Yoke Adjustment The rack-to-pinion lash, or preload, affects steering harshness, feedback, and noise. It is set according to the manufacturer's specifications. An adjustment screw, plug, or shim pack are located on the outside of the housing at the junction of the pinion and rack to correct or set the yoke lash **(Figure 47–11)**.

Tie-Rods Tie-rods in rack and pinion systems are very similar to those used on parallelogram systems. They consist of inner and outer ends. Typically, the rod of the inner tie-rod threads into the outer tie-rod. This allows for changing the length of the tie-rod assembly, which changes wheel position and the toe angle **(Figure 47–12)**. The inner tie-rod ends on rack and pinion units are usually spring-loaded ball sockets that screw onto the rack ends **(Figure 47–13)**. They are preloaded and protected against contaminant entry by rubber bellows or boots.

Manual-Steering Gear

The purpose of the steering gear is to change the rotational motion of the steering wheel to a reciprocating motion to move the steering linkage. In addition, the steering gear also reduces the effort needed to turn the wheels. This is done by using gears of different sizes. The steering gearbox ratio is determined by the total number of degrees of steering wheel rotation divided by the total degrees of movement of the front tires **(Figure 47–14)**. Gearboxes with high numerical ratios, such as 20:1, provide easier but less precise steering. Lower ratios, such as 15:1, provide better driver feedback and feel but at increased effort. A modern full-size truck may have a 20:1 steering ratio and a small sports car, such as the Mazda Miata, around 15.5:1.

There are three styles: the recirculating ball, worm and roller, and the rack and pinion. The latter gear assembly incorporates the already described rack and pinion linkage system and steering gear as a single unit.

The recirculating ball, as shown in **Figure 47–15**, contains a sector shaft, wormshaft, and ball nut. A ball nut is used that has threads that mate to the threads of the wormshaft via continuous rows or ball bearings between the two. Ball bearings recirculate

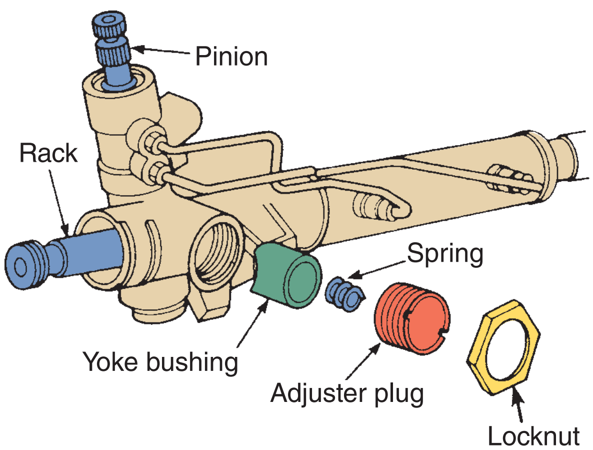

FIGURE 47–11 The rack preload (yoke lash) is adjusted by a screw, plug, or shim pack.

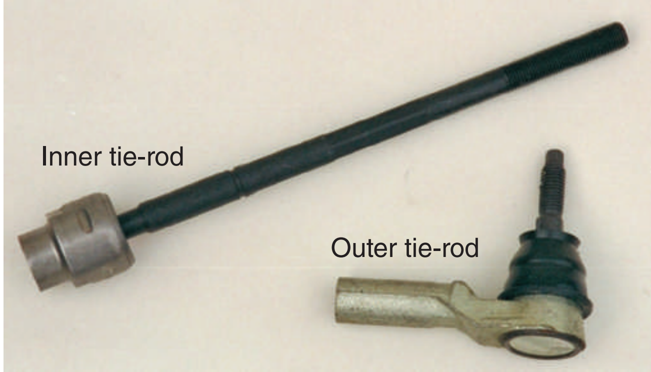

FIGURE 47–12 Rack and pinion inner and outer tie-rods.

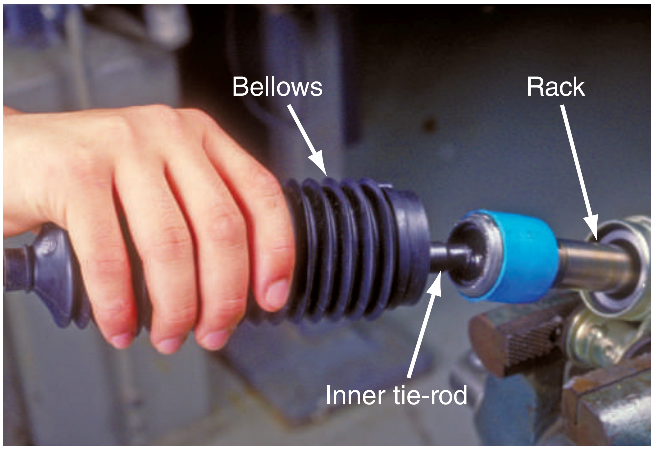

FIGURE 47–13 The inner tie-rod is a spring-loaded ball socket in a rack and pinion steering box.

through two outside loops, referred to as ball return guide tubes. The ball nut has gear teeth cut on one face that mesh with gear teeth on the sector shaft. As the steering wheel is rotated, the wormshaft rotates, causing the ball nut to move up or down the wormshaft. Since the gear teeth on the ball nut are meshed with the gear teeth on the sector shaft, the movement of the nut causes the sector shaft to rotate and swing the Pitman arm.

Variable Steering The number of input turns per output turn of the steering gearbox is called the gearbox ratio. Steering gears can have a constant or a variable ratio. The sector teeth in a constant ratio unit are identical in size and shape, while the sector of a variable ratio unit has larger center teeth **(Figure 47–16)**. This makes the steering faster in turns than in a straight direction. Variable ratio is normally used only in power-steering units.

Steering Wheel and Column

The purpose of the steering wheel and column is to produce the necessary force to turn the steering gear. The exact type of steering wheel and column depends on the year and the car manufacturer. The steering column, also called a steering shaft, relays the movement of the steering wheel to the steering gear. An electric motor, used to provide power steering assist, may be part of the steering column.

Major parts of the steering wheel and column are shown in **Figure 47–17**. The steering wheel is

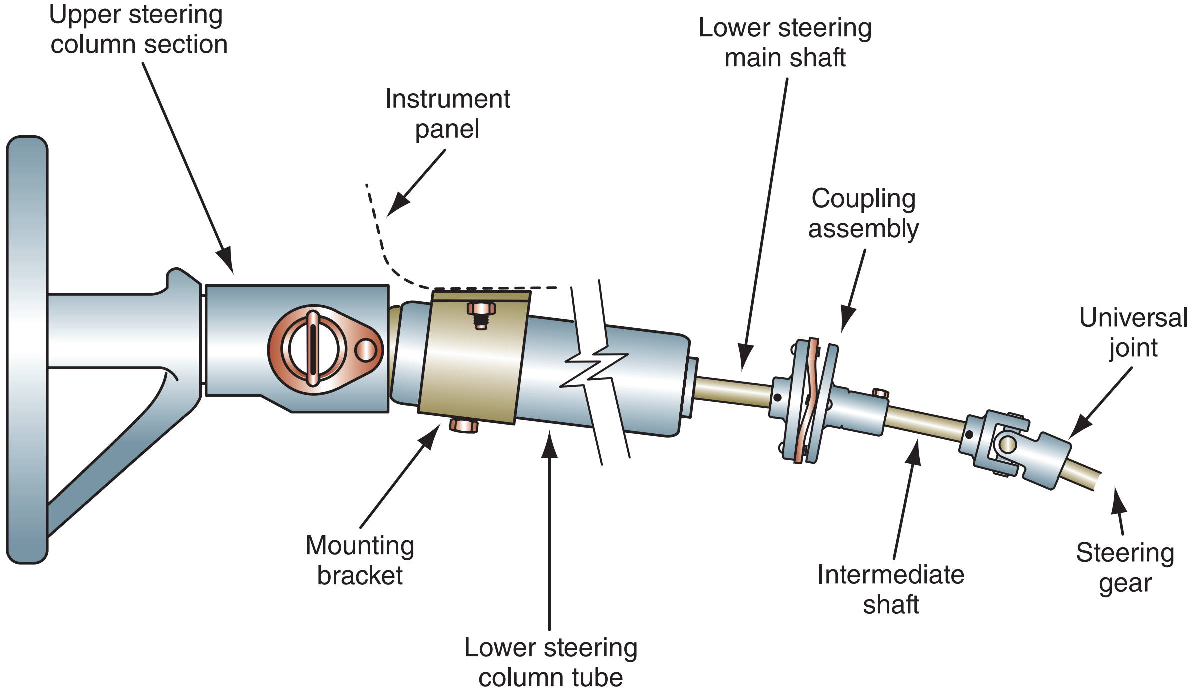

FIGURE 47–17 Typical steering column components. The steering wheel is splined to the shaft that extends through the column and down to the steering gearbox.

used to produce the turning effort. The lower and upper covers conceal parts. The universal joints rotate at angles to connect the steering shaft to the steering gear. Support brackets are used to hold the steering column in place. Assorted screws, nuts, bolt pins, and seals are used to make the steering wheel and column perform correctly. Since 1968, all steering columns have a collapsible feature that allows the column to fold into itself on impact. This feature prevents injury to the driver.

In vehicles equipped with a driver's side air bag, the air bag assembly is contained in the center portion of the steering wheel. This assembly must be disarmed and removed before the steering wheel can be removed.

Warning! **Always follow the manufacturer's service procedures to disarm an air bag before beginning to remove an air bag assembly. Failure to do this may result in accidental air bag deployment. (See Chapter 48 of this textbook.) Air bag service precautions vary depending on the vehicle.**

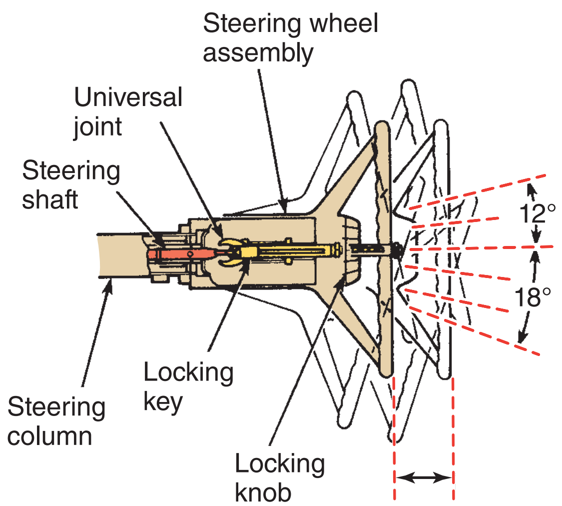

FIGURE 47–18 Tilt steering column operation.

Differences in steering wheel and column designs include fixed column, telescoping column, tilt column, manual transmission, floor shift, and automatic transmission column shift. The tilt columns **(Figure 47–18)** may feature preset detents that have at least five driving positions (two up, two down, and a center position). Many tilt systems allow for setting the position of the column

anywhere between a fixed upper and lower limit. A feature on newer cars and trucks is power tilt and telescoping steering columns. Two small electric motors are used to move the column and wheel into the driver's desired position. One motor is used for tilt while the other motor is for the telescoping function. Powered columns are common on vehicles with programmable memory or personality presets for different drivers.

Most columns contain a multifunction switch, which operates the emergency warning flasher control, turn signal switch, lights (high/low beams), horn, windshield wipers, and washers. Vehicles that use an ignition key often house the key lock cylinder and an antitheft device that locks the steering system in the column. The antitheft device may be a rod, cable, or electric motor used to lock the steering shaft from turning until the key is turned to unlock the column. On automatic-transmission-equipped vehicles, the transmission linkage locks also.

Late-model vehicles with stability control and/or electric power steering assist also have steering sensors located in the column. These sensors are used to determine steering angle and torque and are used as inputs into the electronic power-steering control module and vehicle stability control system.

Methods used to lock the shaft to the tube include a breakaway plastic capsule or a series of inserts or steel balls held in a plastic retainer that allow the shaft to roll forward inside the tube. There is also collapsible steel mesh **(Figure 47–19)** or accordion-pleated devices that give way under pressure. After the vehicle has been in an accident, the steering column should be checked for evidence of collapse. Although the car can be steered with a collapsed column that has been pulled back, the collapsed portion must be replaced. All service information provides explicit instructions for doing this.

Steering wheels often house controls for the audio system, cruise control, communication system, and other systems. The steering wheel is usually held in place on the steering shaft by either a bolt or nut.

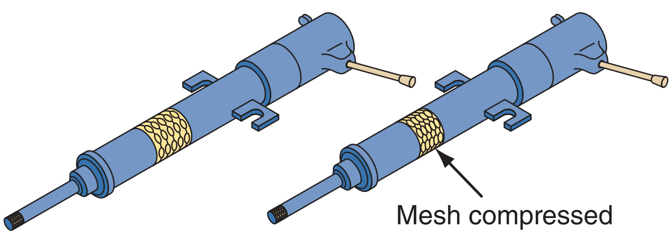

FIGURE 47–19 This figure shows the condition of the collapsible mesh of a steering column before and after an accident.

Power-Steering Systems

The power-steering unit is designed to reduce the amount of effort required to turn the steering wheel. It also reduces driver fatigue on long drives and makes it easier to steer the vehicle at slow road speeds, particularly during parking.

Power steering can be broken down into two design arrangements: conventional and nonconventional or electronically controlled. In the conventional arrangement, hydraulic power is used to assist the driver. In the nonconventional arrangement, an electric motor and electronic controls provide power assistance in steering.

There are several power-steering systems in use on passenger cars and light-duty trucks. The most common ones are the integral-piston, and power-assisted rack and pinion system **(Figure 47–20)**.

Integral Piston System

The integral piston system is used in conventional recirculating ball power-steering systems. It consists of a power-steering pump and reservoir, power-steering pressure and return hoses, and steering gear. The power cylinder and the control valve are in the same housing as the steering gear.

On some model cars and light trucks, instead of the conventional vacuum-assist brake booster, the hydraulic fluid from the power-steering pump is also used to actuate the brake booster. This brake system is called the hydro-boost system **(Figure 47–21)**.

Components

The manual-steering parts described earlier in this chapter, such as the steering linkage, are used in conventional power-steering systems. The components that have been added for power steering provide the hydraulic power that drives the system. They are the power-steering pump, flow control and pressure relief valves, reservoir, hydraulic hose lines, spool valves, and power pistons.

Power-Steering Pump The steering pump is used to develop hydraulic flow, which provides the force needed to operate the steering gear. The pump is belt driven from the engine crankshaft, providing flow

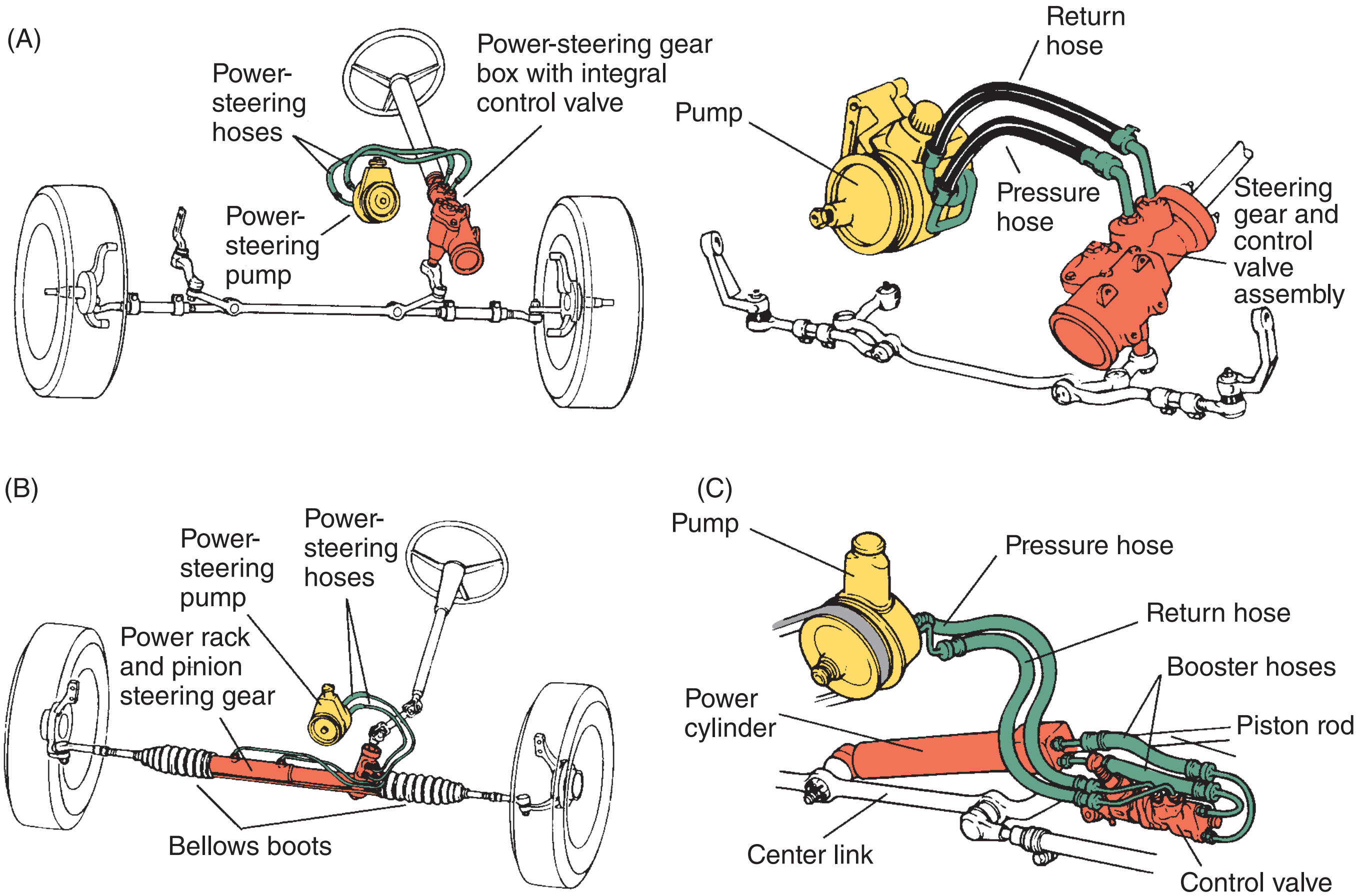

FIGURE 47–20 The three common power-steering systems: (A) Integral-piston linkage. (B) Rack and pinion. (C) External-piston linkage.

any time the engine is running. It is usually mounted near the front of the engine **(Figure 47–22)**. The pump assembly includes a reservoir and an internal flow control valve. The drive pulley is normally pressed onto the pump's shaft.

There are four general types of power-steering pumps: roller, vane **(Figure 47–23A)**, slipper, and gear. Vane pumps are common because of their low internal friction and quiet operation. In a vane pump, the rotor is driven by the pulley when the engine is running. The vanes move outward from the rotor against the inside of the cam ring. Fluid flows into the spaces between the rotor, vanes, and cam ring. As the rotor turns, fluid is trapped in a progressively smaller area. This pressurizes the fluid before it leaves the discharge ports **(Figure 47–23B)**.

Functionally, all pumps operate in the same basic manner. Hydraulic fluid for the power-steering pump is stored in a reservoir. Fluid is routed to and from the pump by hoses and lines. Excessive pressure is controlled by a relief valve.

Power-Steering Pump Drive Belts Many power-steering pumps are driven by a belt that connects the crankshaft pulley to the power-steering pump pulley. Nearly all late-model vehicles use a serpentine belt. This belt may be used to drive all the belt-driven components. Most serpentine belts have a spring-loaded automatic belt tensioner that eliminates periodic belt tension adjustments. The smooth backside of the drive belt may also be used to drive some of the components. Older vehicles use a V-belt to drive the accessories, including the power-steering pump. Regardless of the type of belt, the belt tension is critical. A power-steering pump will never develop full pressure if the belt is slipping.

Electric Power Steering Pump A few vehicles use electrically operated power steering pumps. The advantage is that the pump can be turned off when not actually needed, such as when stopped at a traffic light. This saves fuel and reduces the power drain on the engine.

Flow Control and Pressure Relief Valves A pressure relief valve controls the pressure output from the pump. This valve is necessary because of the variations in engine rpm and the need for consistent steering ability in all ranges from idle to highway speeds. It is positioned in a chamber that is exposed to pump outlet pressure at one end and supply hose pressure at the other **(Figure 47–24)**. A spring is used at the supply pressure end to help maintain a balance.

As the fluid leaves the pump rotor, it passes the end of the flow control valve and is forced through an orifice that causes a slight drop in pressure. This reduced pressure, aided by the springs, holds the flow control valve in the closed position. All pump flow is sent to the steering gear.

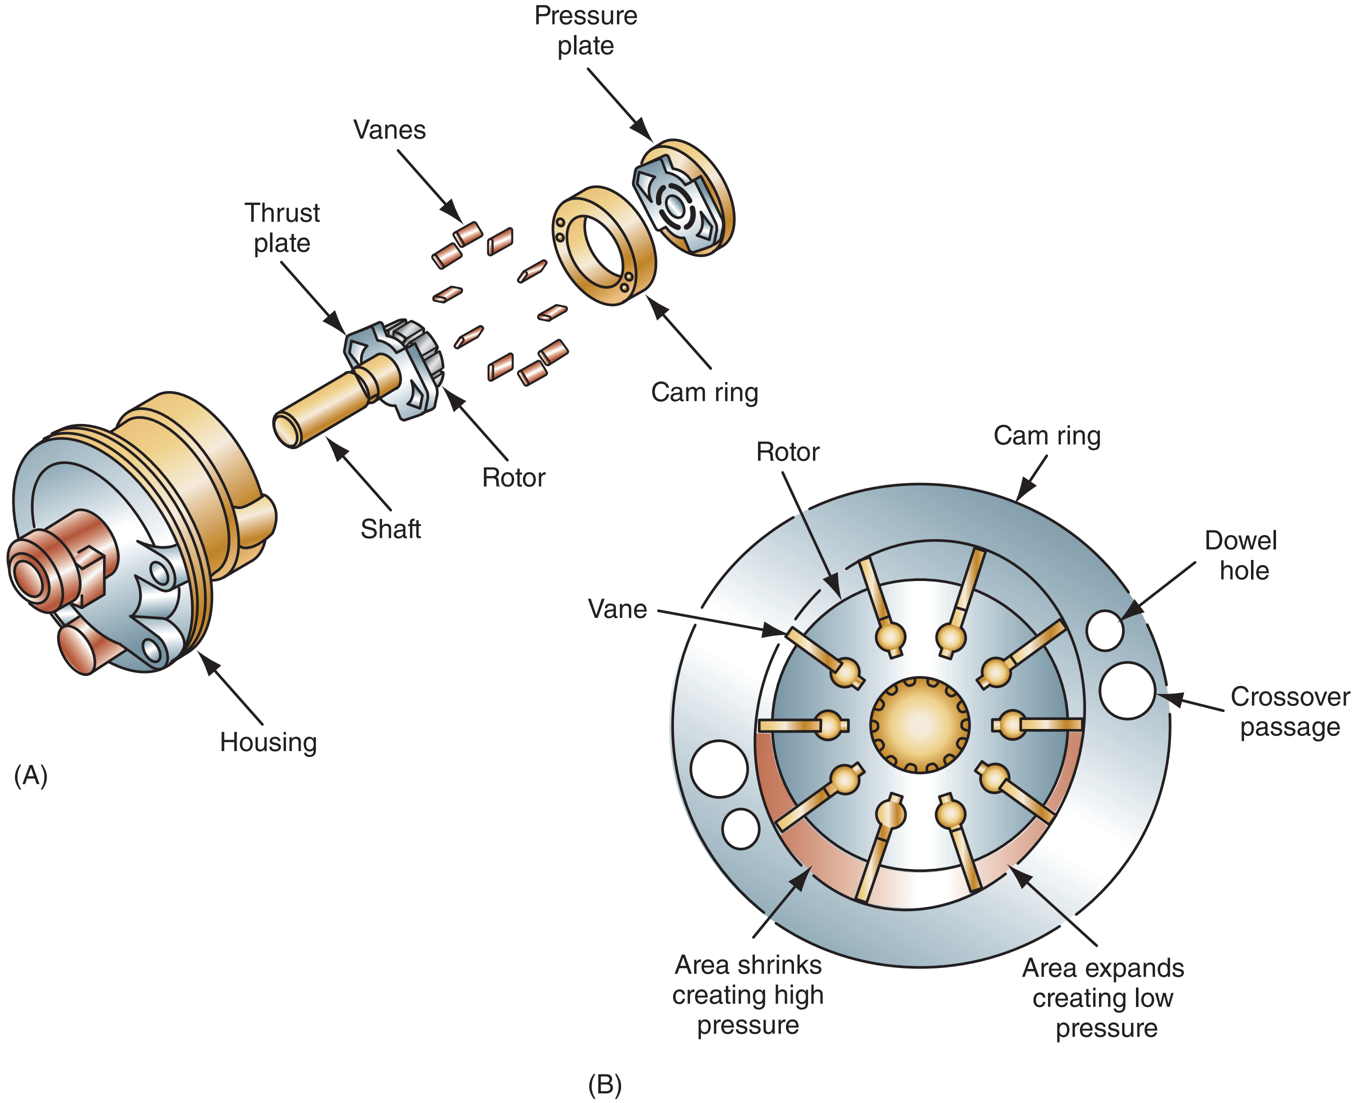

FIGURE 47–23 (A) A vane-type power-steering pump. (B) The basic operation of a vane-type pump.

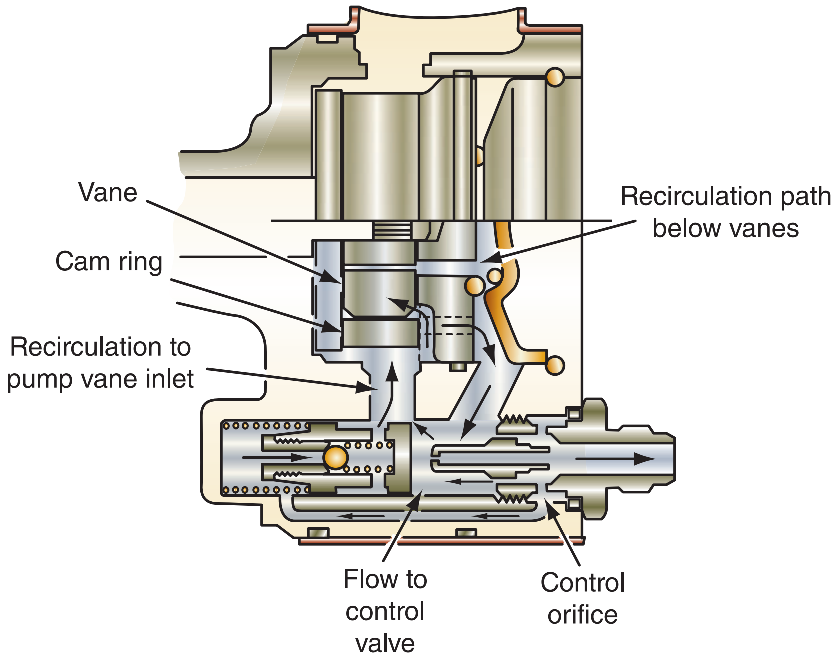

FIGURE 47–24 The flow control valve limits output pressure.

When engine speed increases, the pump can deliver more flow than is required to operate the system. Since the outlet orifice restricts the amount of fluid leaving the pump, the difference in pressure at the two ends of the valve becomes greater until pump outlet pressure overcomes the combined force of supply line pressure and spring force. The valve is pushed down against the spring, opening a passage that returns the excess flow back to the inlet side of the pump.

A spring and ball contained inside the flow control valve are used to relieve pump outlet pressure. This is done to protect the system from damage due to excessive pressure when the steering wheel is held against the stops. Since flow in the system is severely restricted, the pump would continue to build pressure until a hose ruptured or the pump destroyed itself.

When outlet pressure reaches a preset level, the pressure relief ball is forced off its seat, creating a greater pressure differential at the two ends of the flow control valve. This allows the flow control valve to open wider, permitting more pump pressure to flow back to the pump inlet and pressure is held at a safe level.

Some vehicles electronically control the fluid flow from the pump **(Figure 47–25)**. These variable effort systems can decrease fluid flow to increase steering firmness and improve steering feel based on vehicle speed. When vehicle speed is reduced, flow is increased to allow for easier steering.

Power-Steering Gearbox A power-steering gearbox is basically the same as a manual recirculating ball gearbox with the addition of a hydraulic assist. A power-steering gearbox is filled with hydraulic fluid and uses a control valve.

An integral power-steering system has the spool valve and a power piston integrated with the recirculating ball gearbox. The spool valve directs the oil pressure to the left or right power chamber to steer the vehicle. The spool valve is actuated by a lever or a small torsion bar **(Figure 47–26)**.

In parallelogram linkage systems, the control valve is connected directly to the steering linkage through the Pitman arm on the steering gear. Any movement of the steering wheel and the Pitman arm compresses the centering spring and moves the valve spool. This opens and closes a series of ports directing fluid under pressure from the pump to one side or the other of the power cylinder piston **(Figure 47–27)**.

Power-Assisted Rack and Pinion System

Power-assisted rack and pinion components are basically the same as for manual rack and pinion steering except for the hydraulic control housing. The power-assisted rack and pinion system are also similar to the integral system because the power cylinder and the control valve are in the same

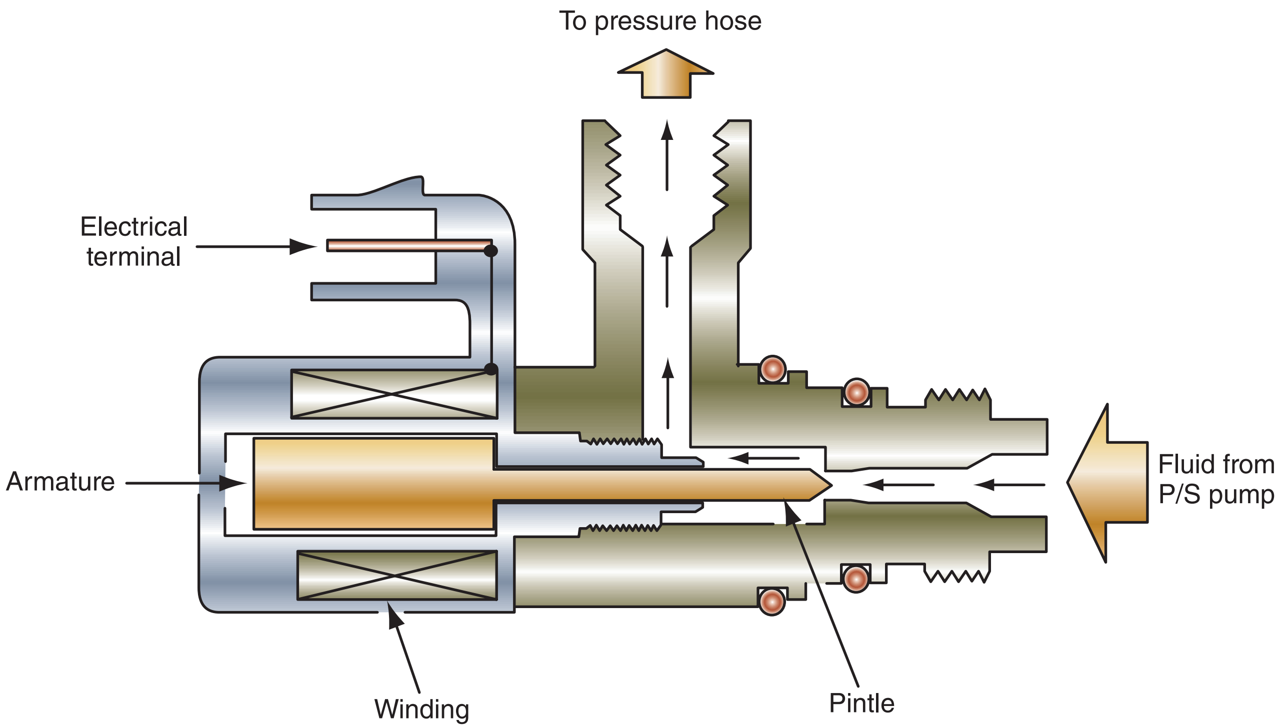

FIGURE 47–25 Electrohydraulic variable effort steering.

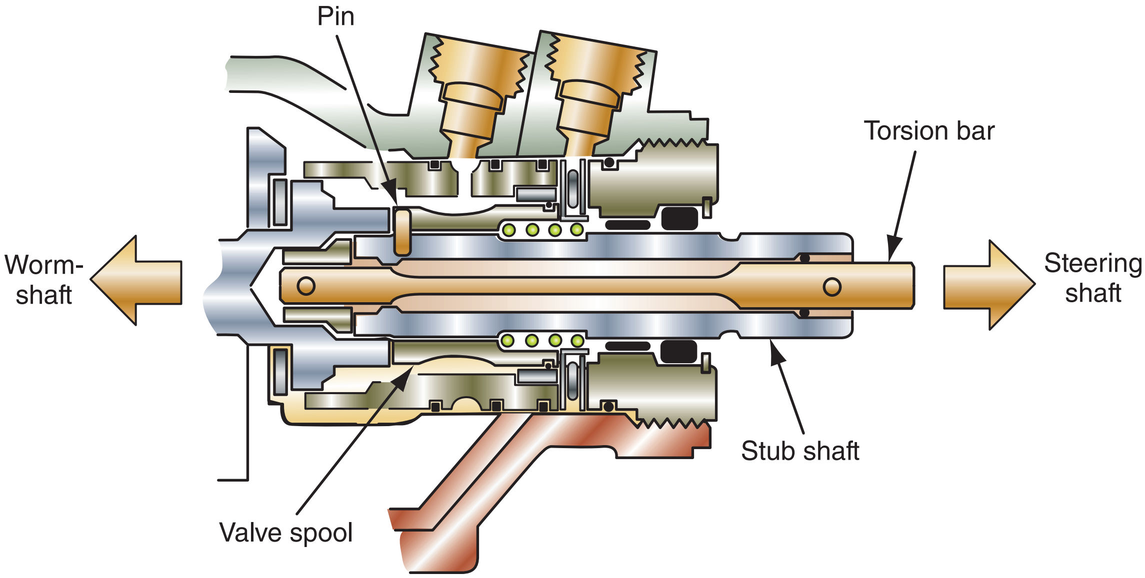

FIGURE 47–26 A torsion bar moves the spool valve to direct the oil flow to the piston.

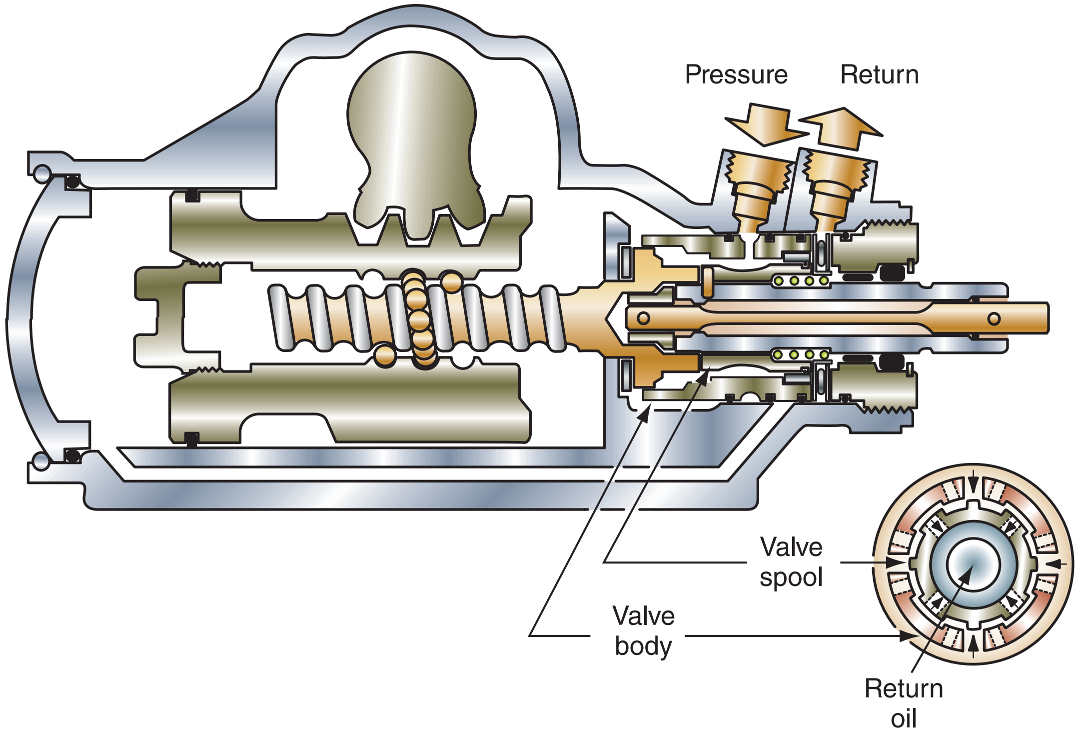

FIGURE 47–27 The spool valve with the wheels straight ahead.

housing. The rack housing acts as the cylinder and the power piston is part of the rack. Control valve location is in the pinion housing **(Figure 47–28)**. Turning the steering wheel moves the valve, directing pressure to either end of the back piston. The system utilizes a pressure hose from the pump to the control valve housing and a return line to the pump reservoir. This type of steering system is common in modern vehicles.

In a power rack and pinion gear, the piston is mounted on the rack, inside the rack housing. The rack housing is sealed on either side of the rack piston to form two separate hydraulic chambers for the left and right turn circuits **(Figure 47–29A)**. When the wheel is turned, the rotary valve creates a pressure differential on either side of the rack piston **(Figure 47–29B)**. This causes the rack to move toward the lower pressure and reduces the total effort required to turn the wheels.

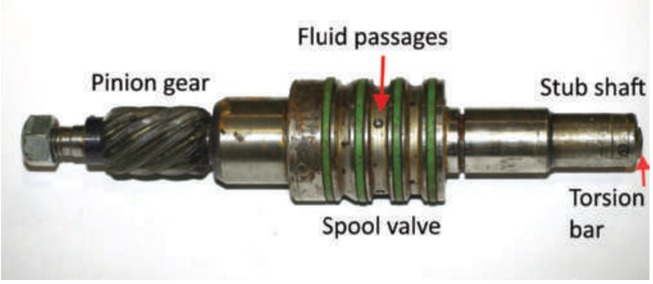

FIGURE 47–28 A pinion gear and spool valve assembly.

Power-Steering Hoses The primary purpose of power-steering hoses is to transmit power (fluid under pressure) from the pump to the steering gearbox, and to return the fluid ultimately to the pump reservoir. Hoses also, through material and construction, function as additional reservoirs and act as sound and vibration dampers.

Hoses are generally a reinforced synthetic rubber (neoprene) material coupled to metal tubing at the connecting points. The pressure side must be able to handle pressures up to 1,500 psi (10,342 kPa). For that reason, wherever there is a metal tubing to a rubber connection, the connection is crimped. Pressure hoses are also subject to surges in pressure and pulsations from the pump. The reinforced construction permits the hose to expand slightly and absorb changes in pressure.

Two internal diameters of hose **(Figure 47–30)** may be used on the pressure side; the larger diameter or pressure hose is at the pump end. It acts as a reservoir and as an accumulator, absorbing pulsations. The smaller diameter or return hose reduces the effects of kickback from the gear itself.

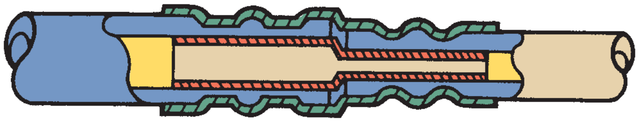

FIGURE 47–30 Power-steering hoses may have two internal diameters.

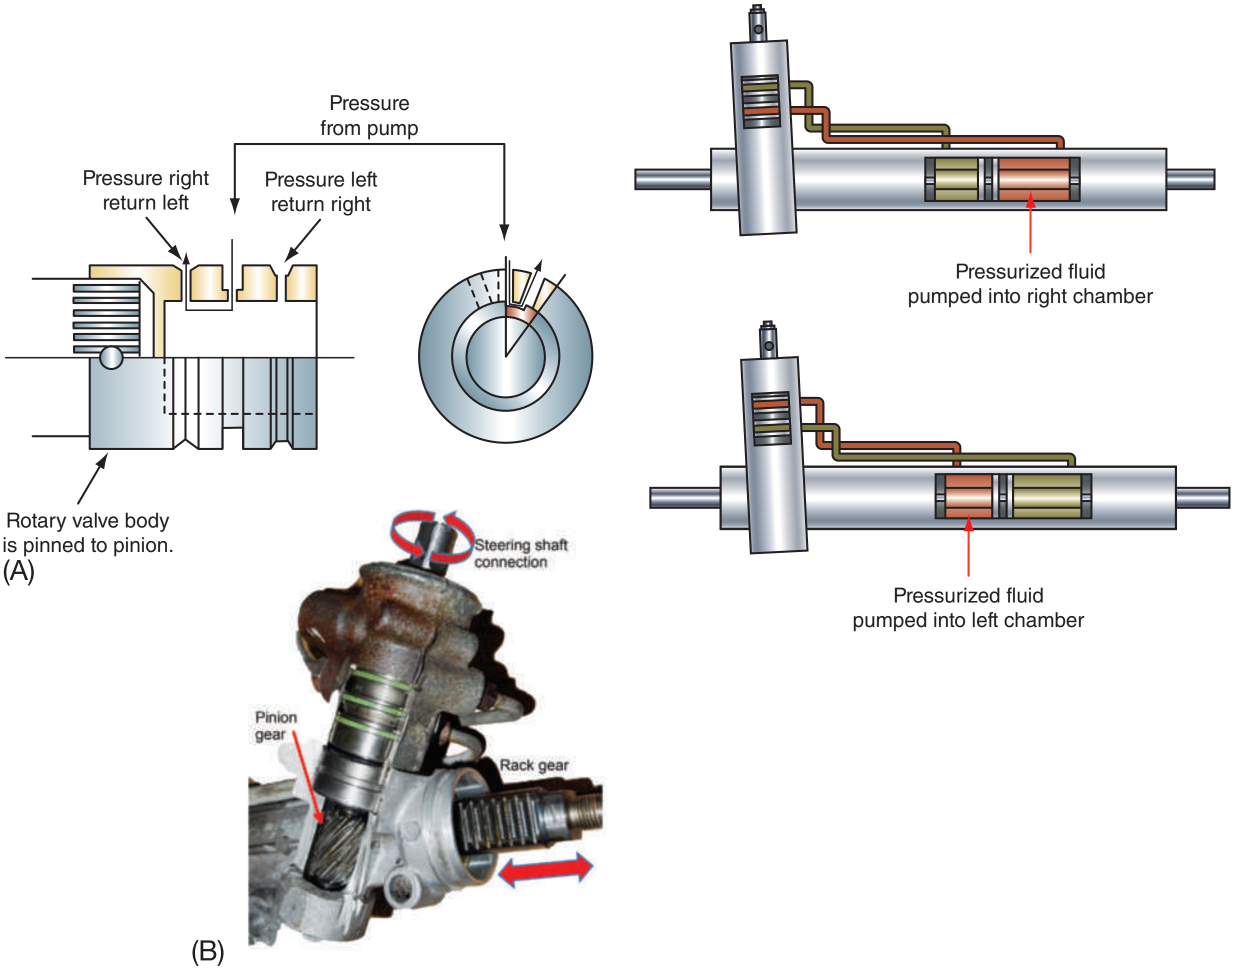

FIGURE 47–29 (A) A power-steering piston and cylinder for a rack and pinion steering gear. (B) The assembly that connects the steering wheel to the rack and pinion assembly.

Caution! Hoses must be carefully routed away from engine manifolds. Power-steering fluid is very flammable. If it comes in contact with hot engine parts, it could start an underhood fire.

By restricting fluid flow, it also maintains constant backpressure on the pump, which reduces pump noise. If the hose is of one diameter, the gearbox is performing the damping functions internally.

Because of working fluid temperature and adjacent engine temperatures, these hoses must be able to withstand temperatures up to 300 °F (150 °C). Due to various weather conditions, they must also tolerate subzero temperatures as well. Hose material is specially formulated to resist breakdown or deterioration due to oil or temperature conditions.

Electronically Controlled Power-Steering Systems

The object of power steering is to make steering easier at low speeds, especially while parking. However, higher steering efforts are desirable at higher speeds in order to provide improved down-the-road feel. The electronically controlled power-steering (EPS) systems **(Figure 47–31)** provide both of these benefits. The hydraulic boost of these systems is tapered off by electronic control as road speed increases. Thus, these systems require well under 1 pound (4.4 N) of steering effort at low road speeds and 3 pounds plus (13.2 N) of steering effort at higher road speeds to enable the driver to maintain control of the steering wheel for improved high-speed handling.

A rotary valve electronic power-steering system consists of the power-steering gearbox, power-steering oil pump, pressure hose, and the return hose. The amount of hydraulic fluid flow (pressure) used to boost steering is controlled by a solenoid valve that is identified as its PCV (pressure control valve).

SHOP TALK The PCV (pressure control valve) is not to be confused with the PCV (positive crankcase ventilation valve) used with emission controls systems.

The electronic power-steering system's PCV **(Figure 47–32)** is exposed to spring tension on the top and plunger force on the bottom. The plunger slips inside an electromagnet. By varying the electrical current to the electromagnet, the upward force exerted by the plunger can be varied as it works against the opposing spring. Current flow to the electromagnet is variable with vehicle road speed and, therefore, provides steering to match the vehicle's road speed.

General Motors' variable effort steering (VES) system relies on an input signal from the vehicle speed sensor to the VES controller to control the amount of power assist. The controller, in turn, supplies a pulse width modulated voltage to the actuator solenoid in the power-steering pump. The controller also provides a ground connection for the solenoid.

When the vehicle is operating at low speeds, the controller supplies a signal to cycle the solenoid faster so it allows high pump pressure. This provides for maximum power assist during cornering and parking. As the vehicle's speed increases, the solenoid cycles less and the pump provides a lower amount of assist. This gives the driver better road feel during high speeds.

MagnaSteer

In the mid-1990s, General Motors introduced magnetic speed variable assist, called MagnaSteer. These systems use a special rack and pinion gearbox that contains an electromagnet inside the spool valve. By varying current flow through the magnet's coil, assist can be increased or decreased. No current flow through the coil maintains a default amount of hydraulic assist.

Active Steering

Active steering improves vehicle stability by turning the wheels more or less sharply than commanded by the turn of the steering wheel during some situations. Through inputs and computer programming, this system can adjust the steering to respond quickly to the threat of skidding **(Figure 47–33)**. The system also allows for a variable steering ratio dependent on vehicle speed.

Current active steering systems are not true steer-by-wire systems. There is still a mechanical connection between the steering wheel and vehicle's wheels **(Figure 47–34)**. The systems have an overriding drive built into the steering column. This drive is controlled by an electric motor, which is

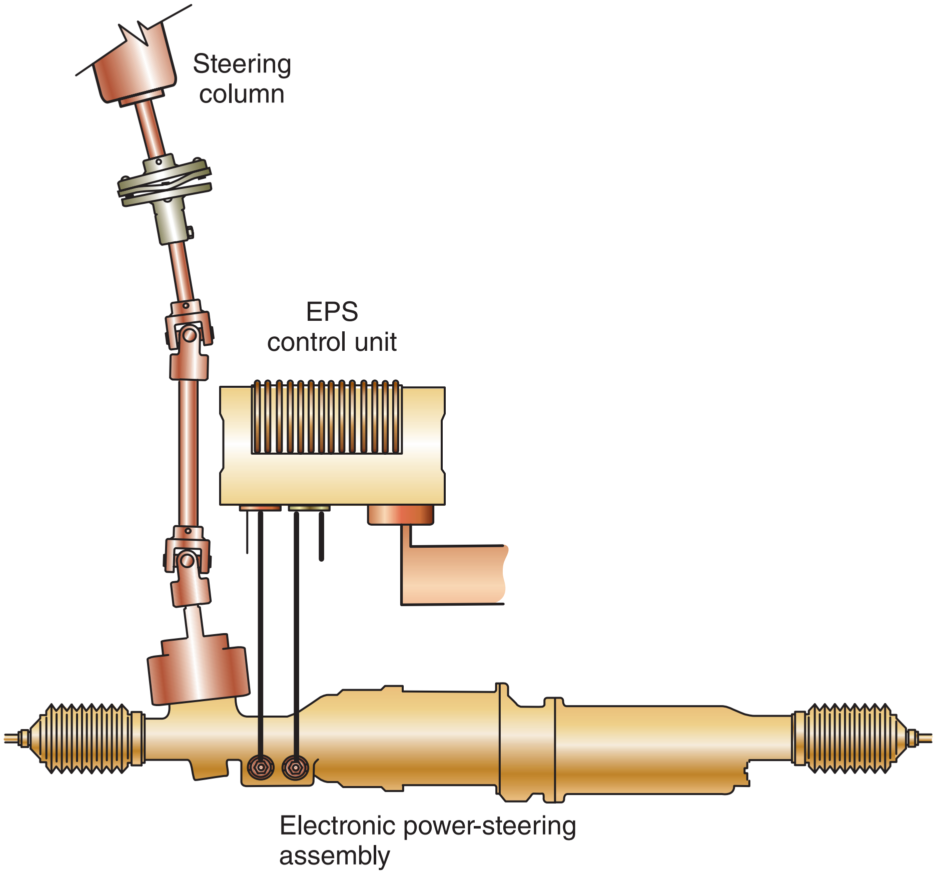

FIGURE 47-31 A variable-assist power-steering system.

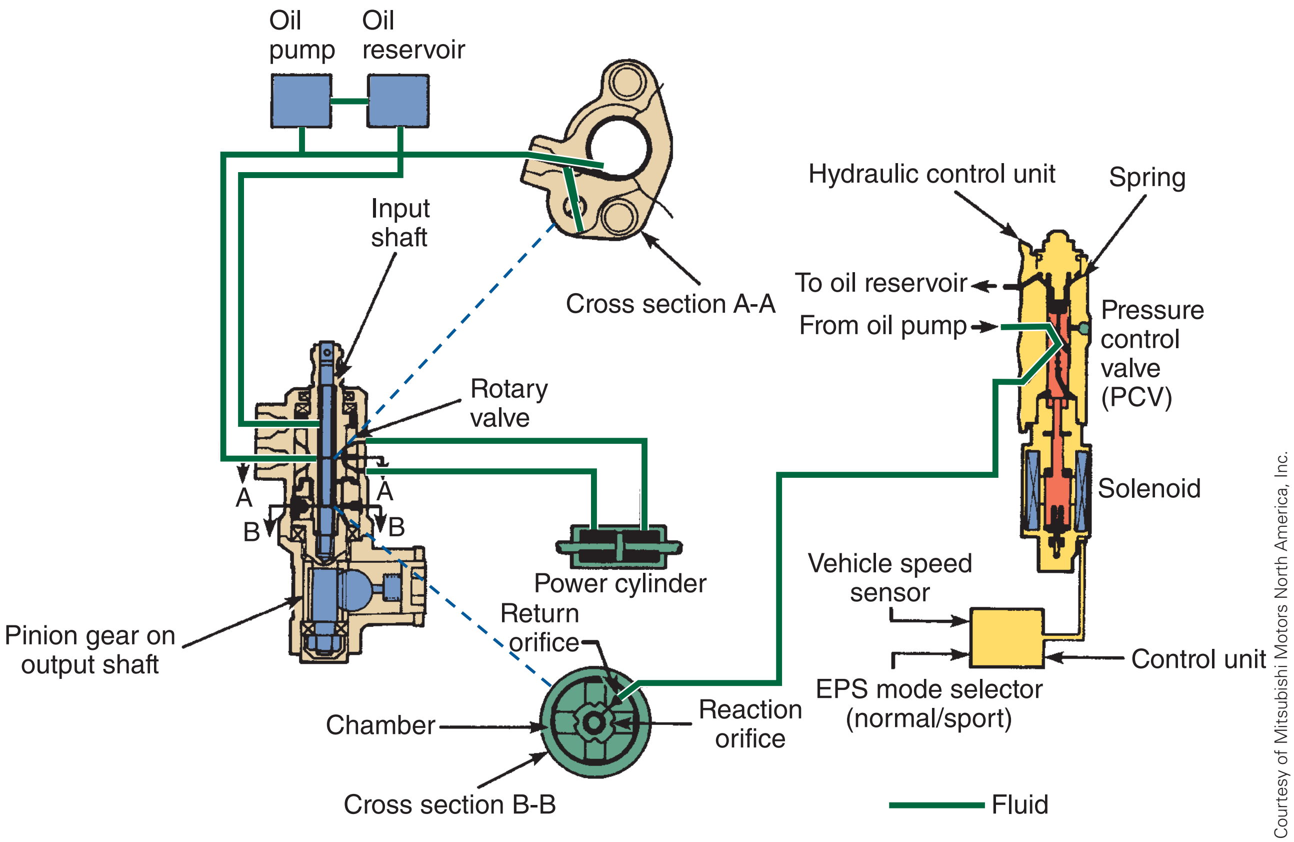

FIGURE 47-32 An outline of electronic power-steering components. The EPS PCV is exposed to spring tension and plunger force.

controlled by the system's computer. The computer determines whether the steering angle needs to be changed and by how much. If the system fails, the planetary gear unit will rotate directly with the steering wheel.

Electric/Electronic Rack and Pinion System

The electric/electronic rack and pinion unit replaces the hydraulic pump, hoses, and fluid associated with conventional power-steering systems with electronic controls and an electric motor. There are three basic types based on where the motor is located. One method is to place the motor concentric to the rack itself **(Figure 47–35)**. The design features a DC motor armature with a follow shaft to allow passage of the rack through it. The outboard housing and rack are designed so that the rotary motion of the armature can be transferred to linear movement of the rack through a ball nut with thrust bearings. The armature is mechanically connected to the ball nut through an internal/external spline arrangement.

Another method of driving the rack gear uses a belt-drive system **(Figure 47–36)**. In this design, the electric motor drives a toothed belt that drives the rack side-to-side with a ball nut type connection. The motor may also be used to directly drive the pinion shaft **(Figure 47–37)**.

The basis of system operation is its ability to change the rotational direction of the electric motor while being able to deliver the necessary amount of current to meet torque requirements at the same time. The system can deliver up to 75 amperes to the motor. The higher the current, the greater the force exerted on the rack. The direction of the turn is controlled by changing the polarity of the signal to the motor.

The field assembly houses permanent ceramic magnets while providing structural integrity for the gear system. In essence, the electronic/electric rack design allows for a direct power source to the rack and steering linkage. The system monitors steering wheel movement through a sensor mounted on the input shaft of the rack and pinion steering gear. After receiving directional and load information from the sensor, an electronic controller activates the motor to provide power assistance.

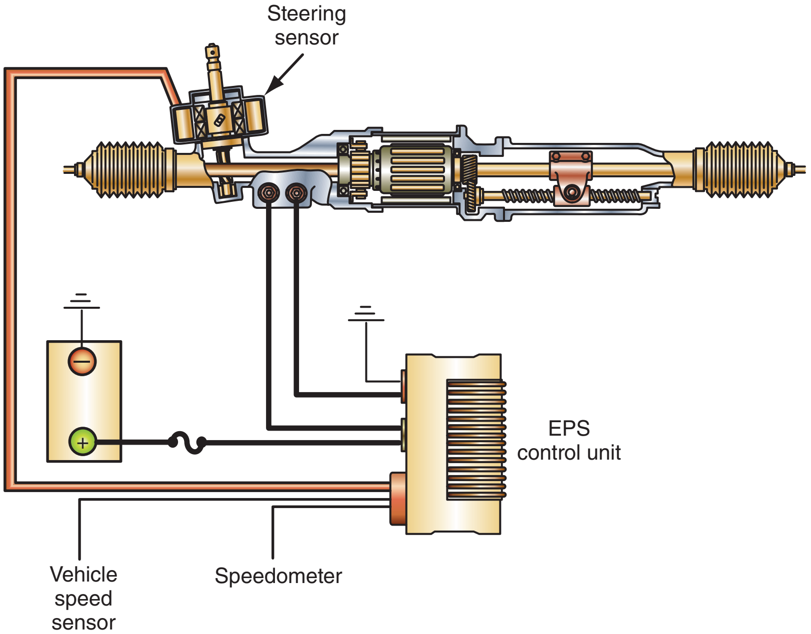

FIGURE 47–35 Electric assist applied with a ball nut to drive the rack gear.

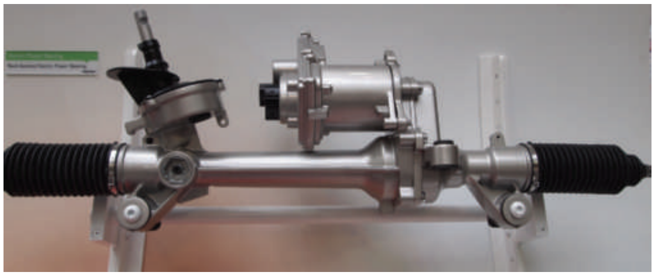

FIGURE 47–36 An external motor and drive belt design.

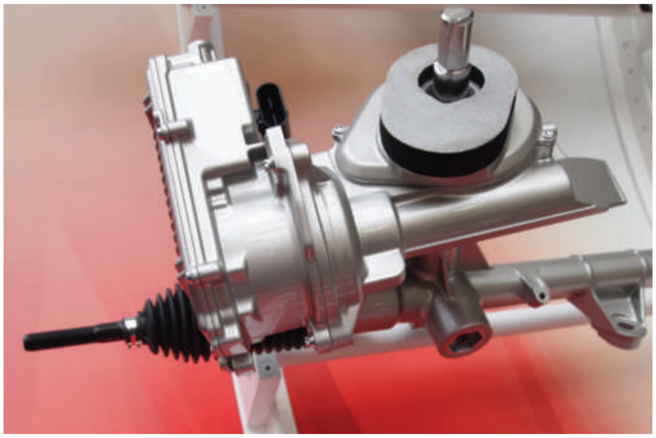

FIGURE 47–37 The motor is used to drive the pinion shaft.

These units are readily retrofitted to conventionally equipped vehicles. As for servicing, there are currently no replacement parts available; therefore, if the rack should become faulty, the entire unit should be replaced. Rebuild kits, with complete installation instructions, are available.

Unlike conventional power steering, electric/electronic units provide power assistance even when the engine stalls, since the power source is the battery rather than the engine-driven pump. The feel of the steering can also be adjusted to match the particular driving characteristics of cars and drivers, from high performance to luxury touring cars. It also eliminates hydraulic oil, which means no leaks.

Column Mounted Power Assist

Many vehicles use column mounted power assist systems. An electric motor is mounted to the steering column and uses a worm gear to directly drive the steering shaft **(Figure 47–38)**. Steering input is detected by one or more torque sensors. As the steering shaft turns, the sensors detect the change in movement. A torsion bar is used in the upper steering shaft. Turning the steering wheel causes movement in the torsion bar and upper torque sensor. The difference in the amount of movement between the two torque sensors is used to determine how to drive the lower steering shaft with the electric motor. The power steering control module (PSCM) uses input from the torque sensors and data from the network to control the torque applied to the steering shaft. Input from other sensors, such as vehicle speed, are used to determine the amount of assist that should be provided by the motor. A high-amperage motor, often a part of the steering module assembly, drives the steering shaft as needed.

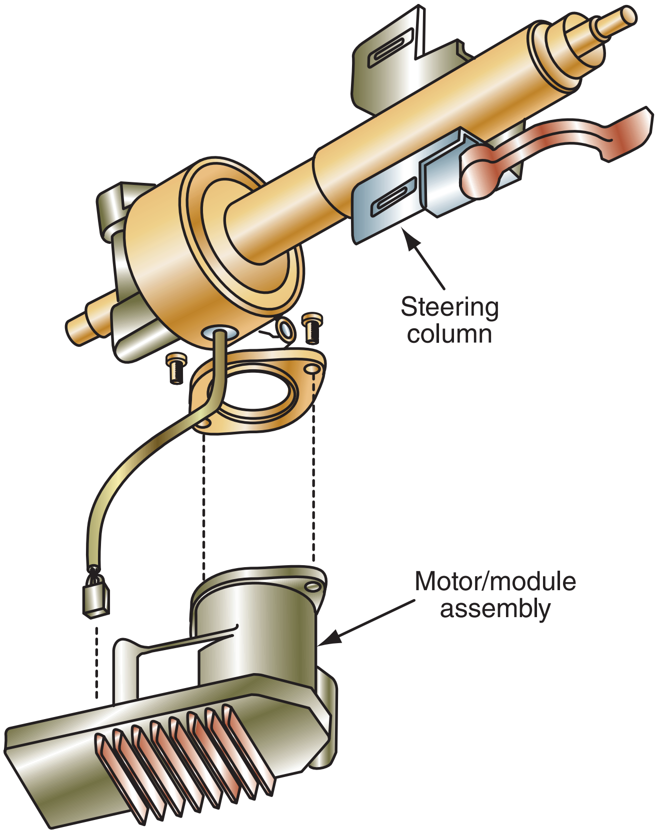

FIGURE 47–38 A column mounted power assist motor.

The electric power steering (EPS) is also incorporated into other systems, such as self-parking, lane monitoring, and lane-keeping assistance. If the vehicle is equipped, input from other systems and networks can be used to command EPS operation. Some newer vehicles will shake the steering wheel if the driver is drifting across the line markers while others will steer the vehicle back into the center of the lane as needed.

Steer-by-Wire System

Steer-by-wire systems **(Figure 47–39)** that completely eliminate the steering column are not yet used on any production vehicles today. However, the Infiniti Q50 has an option, called Direct Adaptive Steering (DAS), which is the next step toward full steer-by-wire. Available since the 2014 model year, the system still retains the mechanical link between the steering wheel and rack and pinon for safety, but the actual steering is handled electronically. In addition to providing variable amounts of assist based on driving speed and driving mode selection, DAS changes the steering ratio, allowing for quicker steering response at higher speeds.

Once implemented, these systems will not use a steering column or shaft to connect the steering wheel to the steering gear. The system is totally

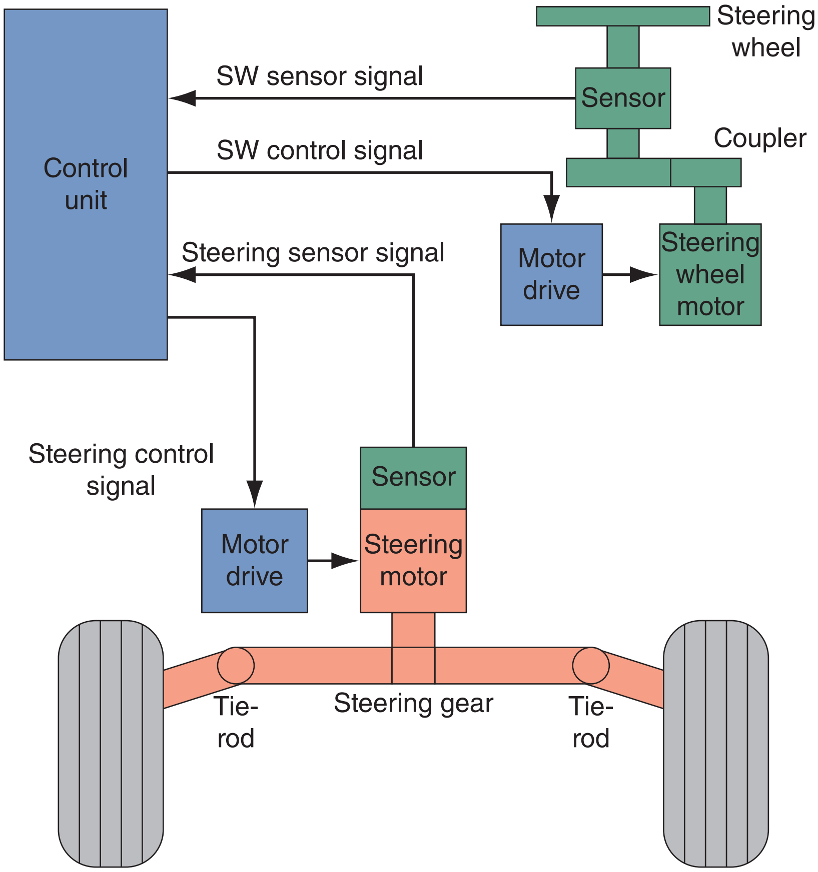

FIGURE 47–39 The basic layout for a steer-by-wire system.

electronic. The turning of the steering wheel is monitored by a sensor. The sensor sends an input signal to a controller. The controller, in turn, sends commands to an electric motor in the steering gear. The commands from the controller are also based on inputs from a variety of other inputs, such as vehicle speed.

A small feedback motor will be used for steering feel. This motor is controlled by a steering controller. This motor provides the correct steering feel for the current conditions. The driver needs this feel to maintain control of the vehicle.

Steer-by-wire systems allow total customization of steering performance and can provide a constantly variable steering ratio. The absence of a steering column opens up space in the vehicle's interior and engine compartment. The systems are also lighter than conventional steering systems.

Steering System Diagnosis

It is important to realize that many steering complaints are caused by problems in areas other than the steering system. A good diagnosis is one that finds the exact cause of the customer's complaint. Although customers may describe the problem in different ways, the most common complaints and their typical causes are discussed next.

Common Complaints

Excessive Steering-Wheel Play Excessive play in the steering wheel is apparent when there is too much steering-wheel movement before the wheels begin to turn. A small amount of play is normal.

This problem can be caused by the following:

- Loose, worn, or damaged steering linkages or tie-rod ends
- Worn ball joints
- Loose, worn, or damaged steering column U-joints
- Loose, worn, or damaged steering column bearings
- Damaged or worn steering gear
- Aerated fluid
- Loose steering gear bolts or faulty rack bushings
- Faulty strut bearing or plate

Feedback When the driver feels the surface of the road through the steering wheel it is called feedback.

This problem can be caused by the following:

- Loose, worn, or damaged steering linkages or tie-rod ends
- Loose, worn, or damaged steering column U-joints
- Loose or damaged steering gear mounting bolts
- Damaged or worn steering column bearings
- Loose suspension bushings, fasteners, or ball joints

A common complaint with electric power assist systems is the lack of feedback. This is due to the system dampening away the feel and feedback from the wheels and tires.

Hard Steering Obviously, a complaint of hard steering results when extra effort is needed to turn the steering wheel. This problem may be simply an absence of power assist. Internal leaks around the flow control valve seals in rack and pinion units is a common cause of hard steering, especially on cold starts. Once the fluid warms, the steering may improve.

This problem can be caused by the following:

- A faulty power-steering pump
- Damaged or faulty steering column bearings
- Seized steering column U-joints
- Steering gearset too tight or is binding
- Stuck flow control valve
- Inadequately inflated tires
- Restricted power-steering lines or hoses
- Blown EPS fuse(s)
- Faulty EPS motor

Nibble This feeling is similar to a shimmy. Nibble results from the interaction of the tires with the road's surface. The customer's complaint may describe the nibble problem as slight rotational oscillations of the steering wheel.

This problem can be caused by the following:

- Loose, worn, or damaged steering linkages or tie-rod ends
- Loose, worn, or damaged suspension parts

Pulling or Drifting A pull is a tugging sensation felt at the steering wheel. The driver must push the steering wheel in the opposite direction of the pull to keep the vehicle going straight. Drifting is a condition in which the vehicle slowly moves to one side of the road when the driver's hands are taken off the steering wheel.

SHOP TALK It must be noted that the steering gear does not cause the vehicle to pull to one side, nor does it cause road wheel shimmy.

These problems can be caused by the following:

- Improper frame or rear axle alignment
- Dragging brakes
- Worn or binding suspension components, especially springs
- Incorrect or uneven wheel alignment
- Unevenly loaded or overloaded vehicle
- Loose, worn, or damaged steering linkages or tie-rod ends
- Out of balance steering gear valve
- Torque steer
- Tire inflation or size differences
- Binding strut bearing
- Unlearned steering angle sensor calibration

Shimmy When the wheels shimmy, the driver will feel large, consistent, rotational oscillations at the steering wheel. These motions are caused by the lateral movement of the tires.

This problem can be caused by the following:

- Loose, worn, or damaged steering linkages or tie-rod ends
- Loose, worn, or damaged suspension parts
- Out-of-balance tires
- Excessive wheel runout
- Tire belt separation or different tread designs on same axle
- Loose wheel bearings

Sticking Steering or Poor Return Poor returnability and sticky steering describes the steering wheel's resistance to return to center after a turn.

This problem can be caused by the following:

- Binding steering column U-joints
- Loose, worn, or damaged steering linkages or tie-rod ends
- Steering gearset too tight or is binding
- Loose, damaged, or worn suspension parts
- Incorrect wheel alignment
- Binding steering column bearings
- Unlearned steering angle sensor calibration

Wandering When a vehicle wanders, the driver must constantly turn the steering wheel to the left and right to keep the vehicle going straight on a level road.

This problem can be caused by the following:

- Loose or worn suspension components
- Incorrect or uneven wheel alignment
- Unevenly loaded or overloaded vehicle
- Loose or damaged steering gear bolts
- Loose steering column U-joint bolts
- Loose, worn, or binding steering linkages or tie-rod ends
- Improper steering gear preload adjustment
- Leaking rack pistons

Diagnosis

As with the diagnosis of any problem, your diagnosis should begin with trying to duplicate the customer's complaint. For steering problems, this is done on a road test; make sure you drive carefully and cautiously, especially because the vehicle has a control problem. It is very important that during the road test the vehicle is driven under conditions similar to the owner's normal driving. Try to duplicate the conditions on which the customer's concern is based. Before going on the road test, do a thorough safety inspection of the vehicle, including the tires.

Once the road test has been completed and it has been determined that there is an abnormal condition, use the symptom to identify the possible trouble area. Then check the parts in that area.

Noise Diagnosis

Often customers complain of abnormal noises or vibrations coming from the steering system. Pay attention to these during the road test. There can be many causes for these; some are not the steering system. The cause of these noises is best identified by paying close attention to where the noise is coming from. Some noises may be caused by tires or interference between the steering wheel and the steering column covers. Others can result from a faulty power-steering pump or system. **Figure 47–40** features a list of common noises and the possible problem areas.

A handy tool for identifying the exact cause of a noise is called the Chassis Ear™ **(Figure 47–41).** This is a wireless electronic device that can identify the

source of a noise during a road test. The unit relies on inductive pickups that clamp on or near the component you want to listen to. The device also has a control unit with adjustable volume and headphones. The value of this tool is that it simply is hard to identify the source of a noise while you are driving.

Visual Inspection

Begin your visual inspection of the steering system by inspecting the tires. Check for correct pressure, construction, size, wear, tread type, damage, and for defects that include ply separations, sidewall knots, concentricity problems, and force problems. Keep in mind that tire wear patterns are good indicators of steering and suspension problems **(Figure 47–42)**. Tire wear is also a great indicator for wheel alignment problems, which is covered in Chapter 48.

Continue your inspection by checking the drive belt for the power steering, if so equipped. Power-steering belt condition and tension are extremely important for satisfactory power-steering pump operation. A loose belt causes low pump pressure and hard steering. A loose, dry, or worn belt may cause squealing and chirping noises, especially during engine acceleration and cornering. The power-steering pump belt should be checked for tension, cracks, oil soaking, worn or glazed edges, tears, and splits. If any of these conditions are present, the belt should be replaced and adjusted properly.

GO TO Chapter 8 for procedures on checking, replacing, and adjusting belt tension.

Also check the fluid level and condition. The fluid is checked at the pump reservoir by observing the fluid level through the reservoir or with the dipstick attached to the reservoir cap. Before checking the fluid, allow the engine to run at idle for 2 or 3 minutes and cycle the steering wheel from lock to lock several times. This warms the fluid to its normal operating temperature and gives a more accurate reading.

Examine the condition of the fluid carefully. Check for evidence of contamination such as solid particles or water. If either of these conditions is present or the fluid has a burnt odor, the system should be flushed.

Also check the fluid for evidence of air trapped in the system. If the fluid looks foamy, it is likely that air is in the system. To verify this, run the engine until it reaches normal operating temperature. Then turn the steering wheel to the left and to the right several times without hitting the stops. If air is in the system, bubbles will appear in the fluid reservoir. Bleeding the system will remove the air.

With the ignition off, wipe off the outside of the power-steering pump, pressure hose, return hose, fluid cooler, and the steering gear **(Figure 47–43)**. Start the engine and turn the steering wheel several times from stop to stop. Check for leaks **(Figure 47–44)**. Fluid leakage will cause abnormal noises and may result in unequal and abnormal steering efforts. If there are no signs of leakage initially, repeat the test several times. While doing this, look at the hoses for signs of swelling. Always replace power-steering hoses with an exact replacement hose. Never attempt to patch or seal a leak in a hose or the hose's fittings.

On all systems, carefully check all mechanical parts of the steering and suspension systems. Many suspension problems can affect the operation of the steering system. If any part is found to be defective it should be replaced.

Power-Steering Fluid

The power-steering fluid can be checked either hot or cold. Fluid level will vary with temperature, however, and a more accurate check is done when the engine is warm. The reservoir cap may have a dipstick **(Figure 47–45)**, which is typically marked HOT

and COLD on opposite sides of the dipstick. Make sure to check the level on the right side of the dipstick. If necessary, add fluid to correct the level. Some manufacturers require a specific fluid for the power-steering system. Always check the service information before installing fluid to the system. Using an incorrect fluid can cause damage to the system and a loss of assist.

Specific Checks

If preliminary checks did not reveal the cause of the customer's concern, detailed checks of the various subsystems and parts should be done.

Power-Steering Pressure Checks

Many steering problems are caused by incorrect pressures in the power-steering system. Most late-model vehicles have a power-steering pressure sensor that can be monitored with a scan tool. In others you must connect a power-steering pressure gauge to the system.

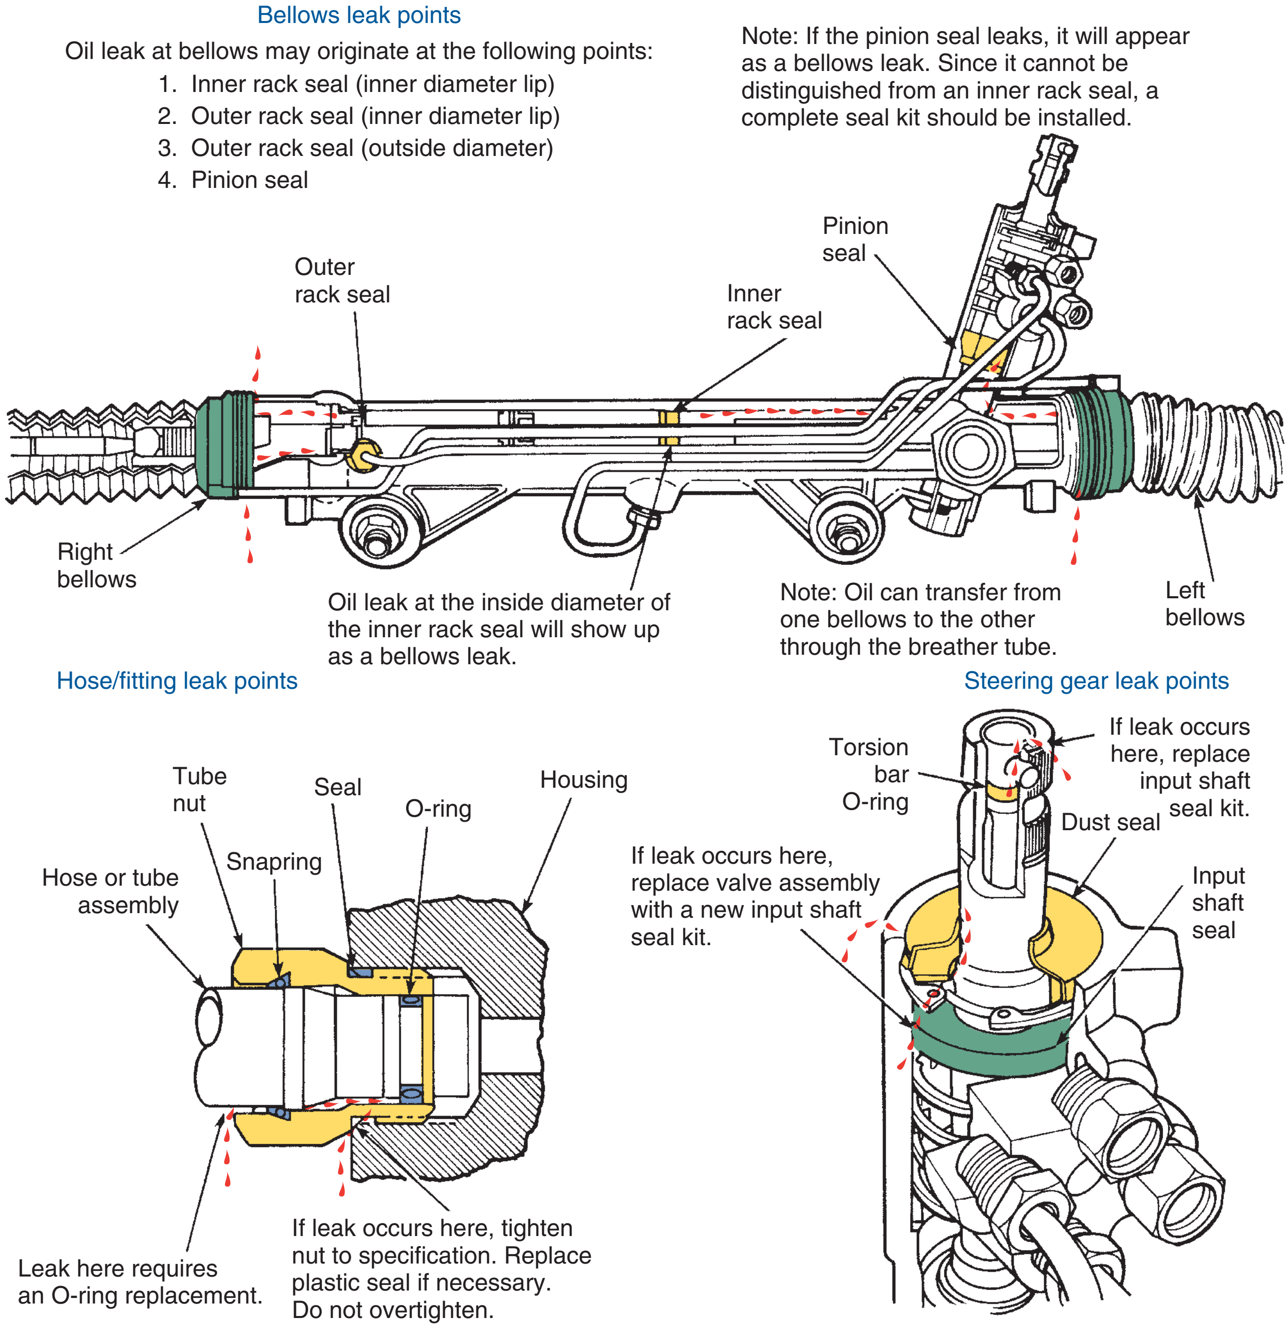

FIGURE 47–44 Possible leakage points on power-steering systems.

Older vehicles may use a pressure switch that only detects low or high pressure. Using a scan tool, the switch may show LOW or OFF under light power steering loads. When the wheels are turned and power steering load increases, the switch may show HIGH or ON. This signals the PCM to boost idle speed to prevent the engine from stalling under low-speed high-power steering demands.

Testing Systems with a Pressure Tester With the engine off, place a drain pan under the vehicle in order to catch any power-steering fluid. Disconnect the pressure hose at the pump. Install the pressure gauge between the pump and the steering gear and bleed the system.

Run the engine for about 2 minutes, and then stop the engine and add fluid to the power-steering pump if necessary. Restart the engine and allow it to idle. Turn the steering wheel and briefly hold it against the steering stops in order to release any trapped air from the system. Observe the pressure reading. The readings should be about 30 to 80 psi

FIGURE 47–45 Check the fluid level with the dipstick attached to the cap.

(200 to 550 kPa). If the pressure is low, the pump may be faulty. If the pressure is too high, the problem may be restricted hoses.

Continue testing by closing the shut-off valve on the gauge and observe the pressure reading **(Figure 47–46)**. When the valve is closed, the pressure should increase. If the pressure is too high, there may be a faulty flow control valve. If the pressure is too low, the pump may be bad. If the flow control valve is suspect, remove and inspect it. If there are any burrs or scratches on the valve, replace it. Do *not* attempt to clean it. Also, inspect the valve's bore. If there are any burrs or scratches, replace the power-steering pump.

After testing and verifying the repairs, remove the gauge, reconnect the lines, refill the system, bleed it, and refill it again.

Electric Power-Steering Systems

Many vehicles, including all hybrid and electric vehicles, have electric power steering. These systems do not have a power-steering pump and require no fluid services. Because these systems are electronically controlled, diagnosis is performed using a scan tool. There is a warning lamp on the dash that comes on when a problem is detected **(Figure 47–47)**. A DTC will also be set. In most cases, when the warning lamp is lit, there will be no power assist available. However, the system will allow for manual steering.

PROCEDURE

Follow these steps to check the pressure in a power-steering system using a scan tool:

STEP 1 Place a thermometer in the power-steering fluid reservoir.

STEP 2 Connect the scan tool.

STEP 3 Set the tool to monitor the power-steering pressure sensor PID.

STEP 4 Start the engine.

STEP 5 With the engine at idle, raise the power-steering fluid temperature to the specified amount by rotating the steering wheel fully to the left and right several times.

STEP 6 With the steering wheel in the straight-ahead position and the engine speed at idle record the pressure reading.

STEP 7 Compare the readings to specifications.

If the pressure reading is higher than specifications, check the power-steering lines and hoses for restrictions.

STEP 8 Turn the steering wheel to the left and right stops. Record the pressure readings at each stop. The pressure reading at both stops should be almost the same. If the pressure reaches the maximum pump pressure at one stop but not the other, install a new steering gear. If the pressure does not reach the maximum pump pressure at either side, install a new pump.

The system is constantly (from key on to key off) monitored by the control module. If a problem is detected, the EPS lamp may stay lit after the ignition is turned on, or it may come on while it is being driven.

Caution! Never hold the steering wheel against its stops for more than 3 to 5 seconds. Doing this can damage the pump.

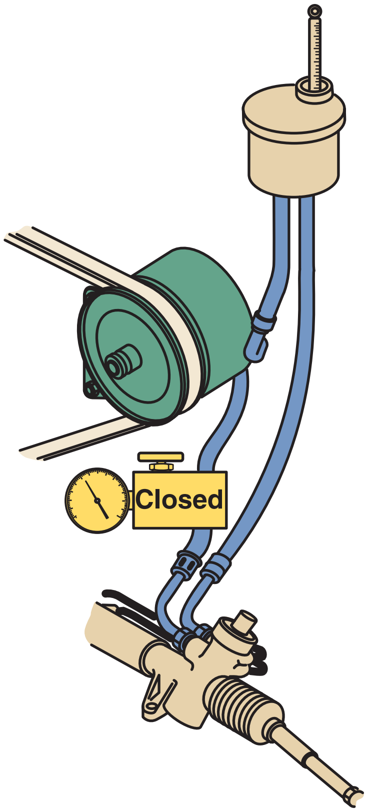

FIGURE 47–46 The final step when checking power-steering pump pressure is to close the tester's valve and observe the pressure in the system. Never keep the valve closed for more than 5 seconds.

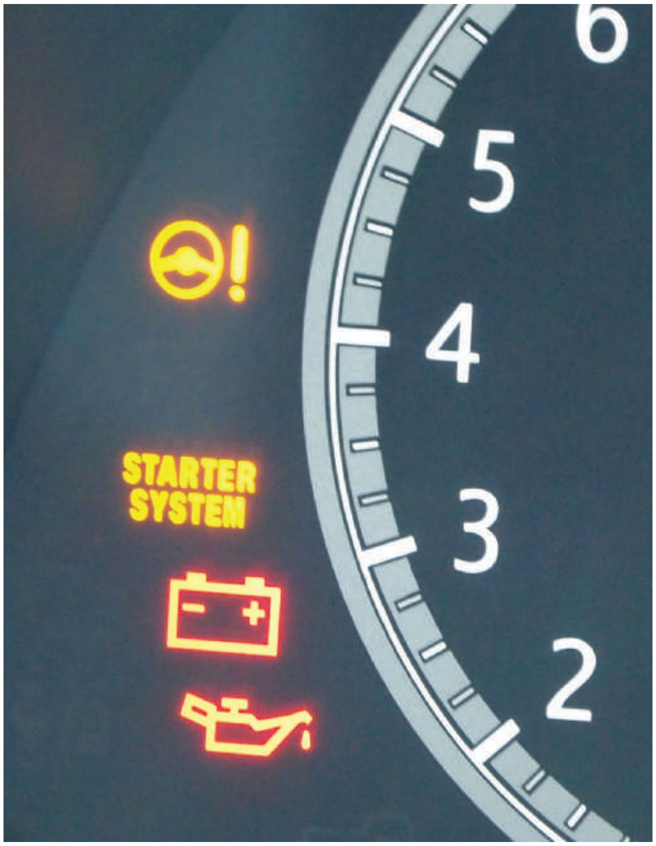

FIGURE 47–47 An electric power-steering fault light.

To identify the reason for the illumination of the lamp, interview the customer to find out when and where it first came on. Try to duplicate the situation during a road test and then retrieve any and all DTCs. If the problem cannot be duplicated, do a careful inspection of all associated wiring and connectors.

Steering problems in an EPS can be caused by the same things as a conventional steering system. However, power assist is provided by electronics, not hydraulics. Therefore, power-steering problems are related to the electronic/electrical components. If the driver complains about how hard it is to turn the steering wheel, the problem can be caused by power-steering motor, speed sensor, power-steering control unit, or electrical circuit problems. For turning effort concerns, inspect the vehicle for damage from hitting curbs or similar obstacles. An impact with a curb can transmit significant force back up the steering linkage and into the EPS motor. If you suspect a problem is with the mechanical components, remove the EPS fuse and perform a test drive. If the problem is still present, the issue is likely not in the EPS itself.

If the steering effort does not change with vehicle speed or is greater when turning left or right, suspect a faulty power-steering motor, speed sensor, or power-steering control unit. A defective power-steering motor may be evident by a high-pitched sound that occurs when the vehicle is stopped and the steering wheel is turned slowly.

On most models, if the power-steering motor gets too hot, the control module will decrease the current flow to it. This can cause increased steering effort. The systems do this to prevent permanent damage to the motor. As soon as the motor's temperature drops, normal current flow resumes. Therefore, a temporary loss of full assist may be normal.

Depending on the vehicle, an electric rack may be able to be serviced and repaired. Some belt-driven rack units can be disassembled and the drive motor and rack replaced separately. However, special tools may be required to reinstall and properly tension the drive belt. Other steering units, and most column-mounted systems are not able to be repaired and the entire unit is replaced.

Be sure to check TSBs and recalls as well. Several manufacturers have EPS bulletins and recalls for control modules, drive motors, and sensors. If the

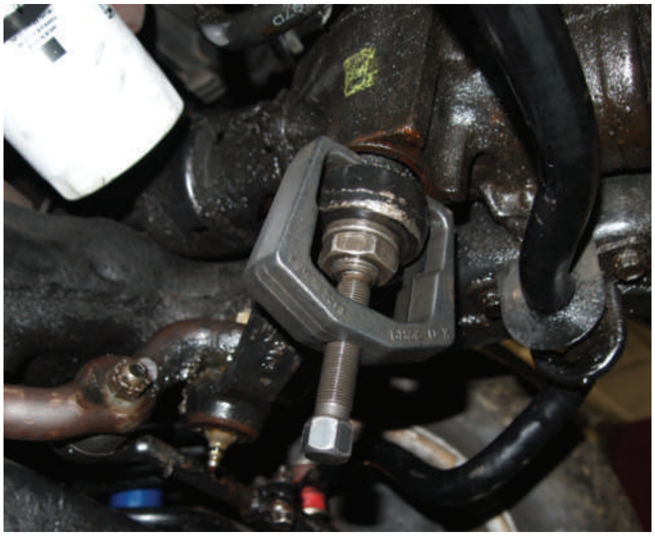

FIGURE 47–48 A Pitman arm puller.

vehicle is under recall, the repairs will be performed by the manufacturer at no charge.

Pitman Arm

Because of its function, the Pitman arm is the most heavily stressed point in the system. To inspect the Pitman arm, grasp it and vigorously shake it to detect any looseness. Check the socket to reveal any damage or looseness. Either condition must be corrected by replacing the worn part. Their removal normally requires the use of a special puller **(Figure 47–48)**.

Idler Arm

Idler arms normally wear more than Pitman arms, with wear usually showing up at the swivel point of the arm or assembly. Worn bushings or stud assemblies on idler arms permit excessive vertical movement in the idler arms.

A worn or damaged idler arm can cause steering instability, uneven tire wear, front-end shimmy, hard steering, excessive play in steering, or poor returnability. Because an idler arm is the weakest link in a parallelogram steering system, it wears more quickly than the rest of the system.

The procedure is simple for checking an idler arm for looseness or wear. The suspension should be normally loaded on the ground or on an alignment rack. When raised by a frame contact hoist, the vehicle's steering linkage is allowed to hang, and proper testing cannot be done. Check the idler arm ends for worn sockets or deteriorated bushings. Grasp the center link firmly with your hand at the idler arm end. Push up with approximately a 25-pound (110-N) load. Pull down with the same load. The allowable movement of the idler arm and support assembly in one direction is $^{1}/_{8}$-inch (3 mm), for a total acceptable movement of ¼ inch (6 mm). The load can be accurately measured by using a dial indicator or pull-spring scale located as near the center link end of the idler arm as possible. Keep in mind that the test forces should not exceed 25 pounds (110 N), as even a new idler arm might be forced to show movement due to steel flexing when excessive pressure is applied. It is also necessary that a scale or ruler be rested against the frame and used to determine the amount of movement. Observers tend to overestimate the actual movement when a scale is not used. The idler arm should always be replaced if it fails this test. Jerking the right front wheel and tire assembly back and forth (causing an up-and-down movement in the idler arm) is not an acceptable method of checking, as there is no control on the amount of force being applied.

Center Link

Worn or bent center links can cause front-end shimmy, vehicle pull to one side, or change in the toe setting, causing excessive tire wear. Center links with stud or bushing ends are likely to become worn from the effects of normal operation and should be inspected periodically. Links with open tapers usually need to be replaced only if they have been damaged in an accident or through excessive tolerance at the mounting position of the idler or Pitman arms.

When inspecting the center link, look closely to insure it has not been bent or damaged. Grasp the center link firmly and try moving it in all directions. Any movement, or sign of damage, is reason for replacement. Tapered openings seldom wear but should be checked for enlargement caused by a loose connection. If necessary, replace the center link.

Tie-Rod Assembly

Tie-rods are subject to wear and damage, particularly if the rubber or plastic dust boots covering the ball stud have been damaged or are missing. Contaminants such as dirt and moisture can enter and cause rapid part failure. A special bonded ball stud, in which no boot is used, is available for use on certain light-duty two-wheel-drive and four-wheel-drive trucks. An elastomer bushing bonded to the stud ball provides strong shock absorption and steering return in downsized vehicles. Worn tie-rod ends

result in incorrect toe-in settings, scalloped and scuffed tires, wheel shimmy, understeering, or front-end noise and tire squeal on turns.

Tie-rod end and center link inspections are similar. Grasp the tie-rod end firmly. Push vertically with the stud, and inspect for movement at the joint with the steering knuckle. Any movement or observation of damaged or missing parts, such as seals, is sufficient evidence that replacement is necessary.

Adjusting sleeves resemble a piece of internally threaded pipe. They have a slot or separation that runs either their entire length or just part way. Adjusting sleeves also have two crimping or squeezing clamps located at each end to lock the toe adjustment. Badly rusted, worn, or damaged adjusting sleeves should be replaced.

An additional check of the tie-rods can be made by rotating each tie-rod end to feel for roughness or binding, which could indicate that the socket has probably rusted internally. A special puller is often required to separate a tie-rod end from the steering knuckle **(Figure 47–49)**.

Steering Damper

The steering dampers found in some steering linkage designs are generally nonadjustable, nonrefillable, and not repairable. At each inspection interval, inspect the mountings and check the assembly for damage (such as being bent) and fluid leaks. A light film of fluid is evidence of fluid leakage. However, a light film of fluid is permissible on the body of the damper near the shaft seal. A dripping damper should be replaced. A bad steering damper may cause wheel shimmy even though the rest of the suspension and steering system is fine.

Dry Park Check

An excellent overall check for worn or loose conventional steering components is the dry park check. With the full weight of the vehicle on the wheels, have an assistant rock the steering wheel back and forth. Start your inspection from one side to the other side. Note any looseness in tie-rod, center link, idler arm, or Pitman arm sockets **(Figure 47–50)**. If a second person is not available, reach up under the vehicle and grasp the flexible coupling on the steering shaft. Rock the linkage.

Turning Effort

If an owner's concern indicates excessive turning effort, a pull scale should be used to read the actual force required to turn the wheel **(Figure 47–51)**.

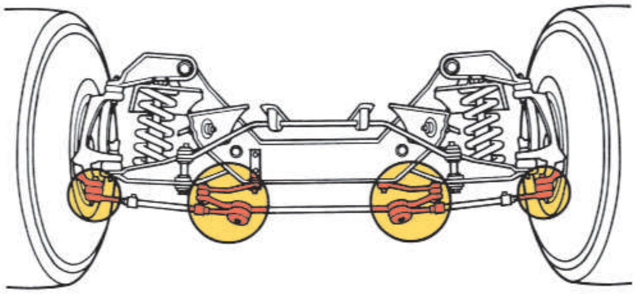

FIGURE 47–50 The circled areas indicate where a dry park check of steering linkage should be made.

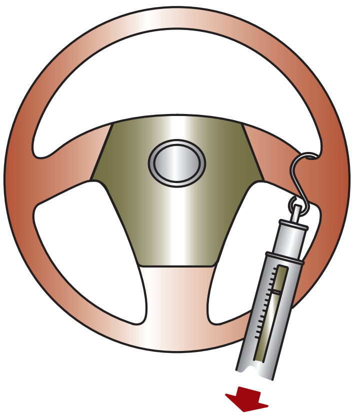

FIGURE 47–51 A pull scale is used to measure steering effort.

Compare the test results to the specifications in the service information. If the effort exceeds the maximum, carefully inspect the entire steering system before performing a pressure test.

Tie-Rod Articulation Effort

The effort required to move the tie-rod or its inner ball socket should be checked with a pull scale if excessive steering effort or looseness is noted during the road test. If the effort is not within the specified limits, the tie-rod must be replaced.

Rack and Pinion Steering

A rack and pinion system has no idler or Pitman arms and no center link. Instead, they are replaced by the rack gear. This reduces the number of wear points on rack and pinion systems to four—each of the tie-rod ends. Power rack and pinion assemblies should be carefully checked for leaks. Leaking rack end seals will allow fluid to accumulate in the bellows **(Figure 47–52)**. Leaks can also be caused by faulty pinion seals and fluid transfer lines. If leaks cause the pump to run out of fluid, the pump will be damaged.

PROCEDURE

Rack and Pinion Steering Inspection

STEP 1 Check all working components **(Figure 47–53)** of the systems. Inspect the flexible steering coupling or the universal joints for wear or looseness. If any play is found, recommend replacement. Universal joints can also seize or bind. They should be checked closely.

STEP 2 Grasp the pinion gear shaft at the flexible steering coupling and try to move it in and out of the gear. If there is movement, the pinion bearing preload might need adjustment. If there is no adjustment, internal components have to be replaced.

STEP 3 Carefully inspect the rack housing. In most cases, the rack and pinion steering assemblies are mounted in rubber bushings. As the vehicle gets older, these mounting bushings deteriorate from heat, age, and oil leakage from the engine. When this happens, the housing moves within its mounting and causes loose and erratic steering. Also, be alert for excessive movement of the rack housing. Stiffness in steering can be caused by a bent rack assembly, tight yoke bearing adjustment, loose power-steering belt, weak pump, internal leaks in the power-steering system, and damaged CV joints in front-wheel-drive vehicles.

STEP 4 Check the inner tie-rod socket assemblies located inside the bellows. The most foolproof way of checking these sockets is to loosen the inner bellows clamp and pull the bellows back, giving a clear view of the socket. During the dry park check, observe any looseness. The inner tie-rod socket can also be checked by squeezing the bellows boot until the inner socket can be felt. Push and pull on the tire. If looseness is found in the tie-rod, it should be replaced. On some vehicles the boot might be made of hard plastic. For this type of boot, lock the steering wheel and push and pull on the tire. Watch for in-and-out movement of the tie-rod. If movement is observed, replace the inner tie-rod.

One fact to keep in mind is that the condition of the bellows boot determines the life of the inner socket. The bellows boot protects the rack from contamination. If any cracks, splits, or leaks exist, the boot should be replaced. Also, be sure that clamps for the bellows are in their proper place and fastened tightly.

STEP 5 Inspect the outer tie-rod ends. In addition to the dry park check, grab each end and rotate to feel for any roughness that would indicate internal rusting. Be sure to check for bent or damaged forgings and studs, split or deteriorated seals, and damaged, out-of-round, or loose tapers. If any of these conditions exist, the parts should be replaced.

FIGURE 47–52 A leaking rack seal.

In order to solve customer complaints, a very thorough inspection of the entire system is needed. Everything, including ball joints, tires, outer tie-rods, bellows boots, inner tie-rods, rack-mounting bushings, mounting bolts, steering couplings, and gearbox adjustment must be checked. Rack and pinion steering inspection must be very thorough because of the system's sensitivity.

Steering System Servicing

When a steering system component is found to be faulty, it is replaced. Most often part replacement is quite straightforward but you should always refer to the service information before proceeding. Also check the TSBs for any updated parts or procedures. At times, diagnosis will indicate a need to adjust the steering gear or inspect and repair the steering column.

Steering Linkage

Eventually, steering linkage components wear and require replacement. Removing tie-rods and center links is straightforward. First, remove the nut securing the stud. This may require removing and discarding a cotter pin. Next, break the taper between the stud and component it is connected to. This is often done using a tie-rod puller or "pickle fork." However, do not use a pickle fork or hammer on aluminum parts. Use a ball joint separator so that the aluminum is not damaged. Once the part is removed, install the new component and torque the nut to specifications.

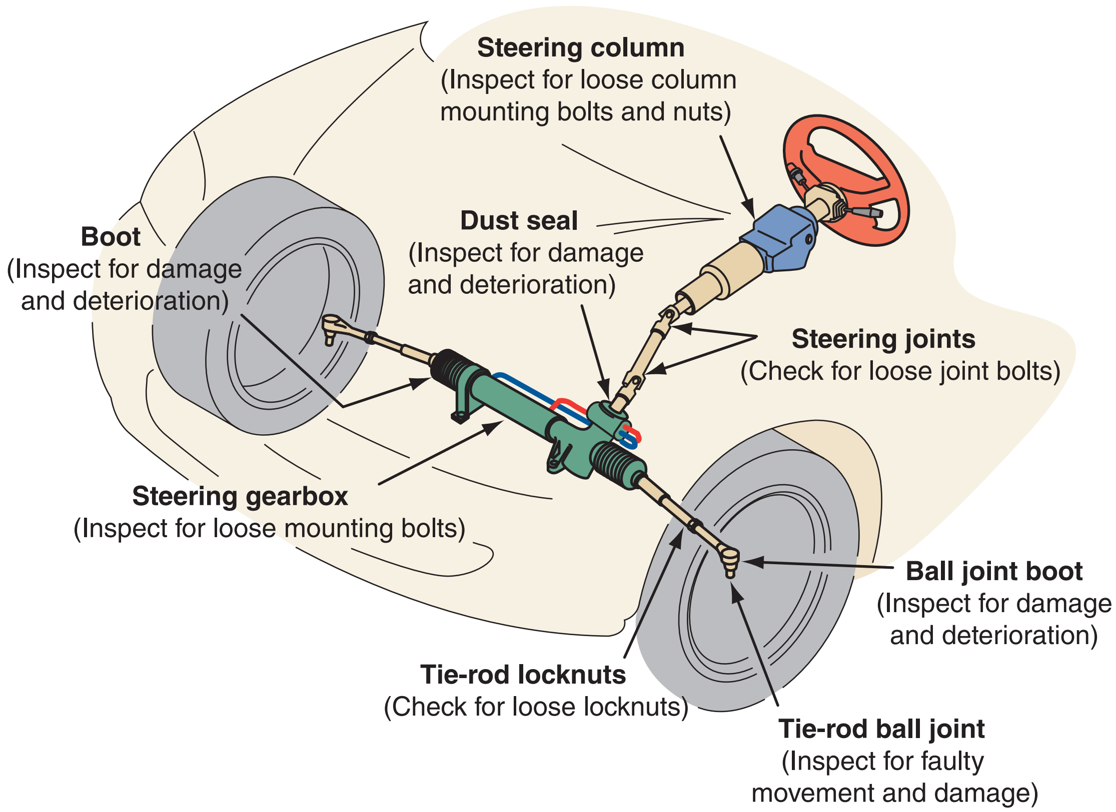

FIGURE 47–53 All steering parts should be carefully checked during diagnosis.

If a castle nut and cotter pin are used and the nut does not align with the hole in the stud, tighten the nut until it aligns, then install a new cotter pin. Bend one or both of the free ends to prevent the pin from working loose and falling out.

To replace an idler arm, remove it from the center link and then unbolt the arm from the frame. Install the new arm and torque the bolts and nuts to specifications. To replace a Pitman arm, first remove the retaining nut and washer. Next, install a Pitman arm puller over the arm and tighten the shaft against the Pitman shaft. Pitman arms tend to be tight so do not be surprised if it takes a bit of work to get it loose from the gearbox. Once off, install the new Pitman arm, washer, and nut. Tighten the nut to specifications.

Before assembling any steering linkage parts, thoroughly check all tapered holes for out-of-roundness and wear. Thoroughly clean all bores where the stud tapers set in. On new and reused parts, firmly install the tapered stud into its tapered hole. The stud must seat firmly without rocking. Only the threaded area should protrude from the hole. If the parts do not meet these requirements, the mating part is worn and must be replaced, or the correct parts are not being used. Always follow the manufacturer's stud and mounting bolt torque specifications when installing chassis parts.

Rack and Pinion Inner Tie-Rods

For end take-off rack and pinion units, removing the inner tie-rods begins by pulling the outer tie-rod ends from the steering knuckle. Measure and note the position of the tie-rod and jamb nut on the inner tie-rod. This will make setting the toe a little quicker if it is already close to where it was before the tie-rod was replaced. Loosen the jam nut securing the inner and out tie-rods tight and then unthread the outer tie-rod from the inner. Remove the jam nut and then the clamps holding the bellows to the inner tie-rod and the rack housing. Pull the bellows off the rack and inspect it for cracks or other damage.

Check the service information for tie-rod removal. Some tie-rods have set screws or staked washers that must be removed first. Also, some manufacturers require that the rack gear be held from moving when loosening the tie-rod. Photo Sequence 45 shows the typical procedure for replacing an inner tie-rod on a rack and pinion steering system.

Removing the inner tie-rod often requires a special tool, shown in Photo Sequence 45. The tool is placed over the tie-rod; make sure it fits snugly. Attach a ratchet to the tie-rod socket and remove the tie-rod. Tighten the inner tie-rod to specifications and reinstall any set screws or other retention devices as outlined in the service information. Tighten the outer tie-rod nut to specifications and install a new cotter pin. If the outer tie-rod uses a nylon friction nut to secure it to the steering knuckle, do not reuse the nut. Install a new nut and torque it to specs. Once the tie-rod is installed, the toe will need to be checked and adjusted.

Steering Gear Adjustments

Before any adjustments are made or servicing procedures performed to the steering gear, a careful check should be made of front-end alignment, shock absorbers, wheel balance, and tire pressure for possible steering system problems.

Before adjusting or servicing a manual steering gear, you may need to disconnect the battery ground cable. Raise the vehicle with the front wheels in the straight-ahead position. Remove the Pitman arm nut. Mark the relationship of the Pitman arm and shaft. Remove the Pitman arm with a Pitman arm puller. Loosen the steering gear adjuster plug lock nut and back the adjuster plug off one-quarter turn **(Figure 47–54)**. Remove the horn shroud or button cap. Turn the steering wheel gently in one direction until stopped by the gear; then turn back one-half turn. Measure and record bearing drag by applying a torque wrench with a socket on the steering wheel nut and rotating through a 90-degree arc. Check the service information for the correct amount of drag.

Once these steps are taken, the steering gear is ready for adjusting or servicing as per instructions in the vehicle's service information.

Rack and Pinion Service

When removing a rack and pinion steering gear, realize that the procedure for doing this will vary with the

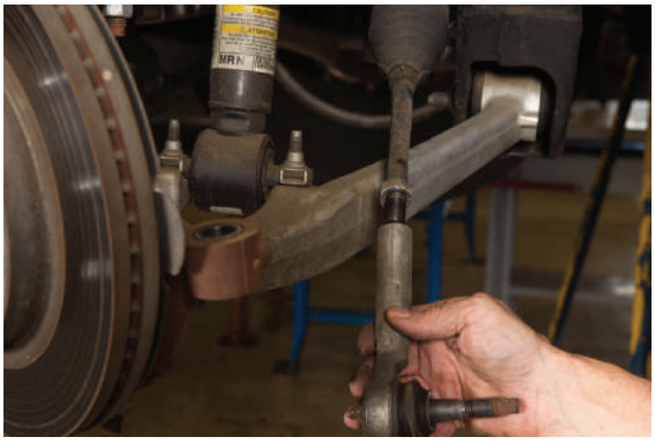
Replacing Inner Tie-Rod on a Rack and Pinion

P45-1 Remove the wheel and tire to gain access to the tie-rods. Thread the lug nuts back onto the wheel studs.

P45-2 Loosen the jam nut that locks the inner and outer tie-rods together.

P45-3 Next, remove the nut holding the outer tie-rod to the steering knuckle. Some vehicles use a cotter pin to retain the nut; discard the cotter pin since a new pin will be used during reassembly. If a nylon lock nut is used, a new nut will be needed.

P45-4 Using a tie-rod end remover, separate the tie-rod from the steering knuckle. Be careful not to damage the outer tie-rod end since it is not being replaced.



P45-5 Once the outer tie-rod is removed from the knuckle, thread the outer tie-rod and jam nut from the inner tie-rod.

P45-6 Next, remove the clamp from the small end of the bellows.

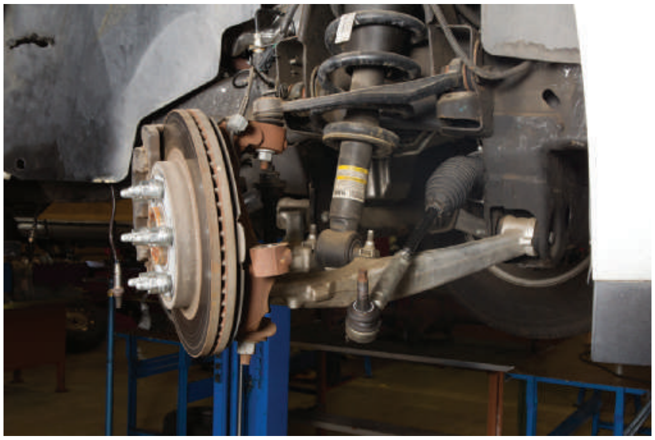
P45-8 With the bellows removed, the connection where the inner tie-rod threads onto the rack gear is visible.

P45-9 Depending on the vehicle, there are several different tools available for removing and installing the inner tie-rod.

P45-10 Use a ratchet and the inner tie-rod tool to remove the tie-rod. Refer to the service information to determine if the rack gear needs to be supported when removing the inner tie-rod.

P45-11 Compare the old and new tie-rods and make sure the replacement tie-rod is correct.

P45-12 Locate the inner tie-rod tightening spec and torque the tie-rod to the manufacturer's specification.



P45-13 Reinstall the bellows and secure it in place; use new clamps if necessary. Reinstall the jam nut and outer tie-rod end. Torque the outer tie-rod to specs and reinstall the wheel and tire. Be sure to check the wheel alignment since the toe is going to need adjustment.

model and make of the vehicle; always refer to the procedures outlined by the manufacturer. First, make sure the front wheels of the vehicle are in the straight-ahead position and the steering wheel is locked. A typical procedure includes removing the wheels and disconnecting the outer tie-rods from the steering knuckles. Next, remove hydraulic pressure and return lines at the rack. Do not remove the transfer lines unless they obstruct access to other items. Disconnect any electrical connectors from the rack. Locate the clamp that secures the steering shaft to the pinion shaft. The clamp is typically covered by a protective boot that may be secured to the body of the vehicle where the column passes through the fire wall. Remove the clamp bolt and slide the clamp off of the pinion shaft. Remove the rack mounting bolts and remove the rack. The rack may have to pass through the wheel opening in the body or in some cases, the cradle may have to be lowered or the engine and/or transaxle must be removed to remove the rack.

Typically a faulty rack is replaced and internal repairs are not made. However, if it is necessary to disassemble and inspect the assembly, the rack should be secured in a vise or the special tool recommended by the manufacturer. Once it is secured, all fluid transfer tubes can be removed, along with the tie-rod ends and boots. Check the boots for cracks or signs of leakage; replace them, if damaged.

Warning! **It is easy to damage the boots and the rack while disassembling the unit, so be careful and adhere to all of the manufacturer's recommendations.**

Make an index mark on the outer tie-rod end, jam nut, and tie-rod **(Figure 47–55)**. Remove the rack guide spring cap, compression spring, and rack guide subassembly. Then remove the O-ring from the rack guide spring cap and the dust cover. Now remove the control valve assembly and subassembly. In some cases the subassembly is removed by pressing it away from the main assembly. Once the subassembly is separated, remove the snaprings, seals, and spacers from it.

FIGURE 47–55 Before disassembling the steering gear, make an index mark on the outer tie-rod end, jam nut, and tie-rod.

The cylinder and "stoppers" in the rack are removed next, along with the steering rack bushing. When doing this, be careful not to drop the bushing or damage the inside of the steering gear housing.

Check the following:

- *Inner Tie-Rod Sockets.* If the inner tie-rod ends were found to be loose during the inspection or if they require too much effort to move, replace them.
- *Pinion and Bearing Assembly.* If the pinion bearing is loose on the shaft, replace the pinion and bearing assembly. A pinion shaft with worn or chipped teeth must be replaced. Inspect the pilot bearing contact area on the pinion shaft. Wear, pitting, or scoring in this area indicates that a new pinion shaft is required. If the pinion bearing is bad, replace the pinion shaft and bearing assembly.
- *Rack Bushing.* If the rack bushing is worn, bushing replacement is necessary.
- *Mounting Bushings.* If the mounting bushings are loose, replace the bushings. Always replace the bushings in pairs. If the bushings are in satisfactory condition, do not disturb them. Work rack bushings can cause noise and bump steer concerns.

SHOP TALK

Some manufacturers actually recommend different lengths for the torque wrench that is used to measure, test, and tighten things. This is a reason for always checking the manufacturer's recommendations before proceeding with a repair or service. For example, Toyota recommends using a torque wrench with a different fulcrum length for different applications. Torque wrenches with a fulcrum length of 9.84 inches (250 mm) or 11.81 inches (300 mm) are recommended to measure interference and tightening. Always check the service information for the correct procedures.

When installing new parts to the rack assembly or when reassembling the unit, all moving parts should be lubricated with power-steering fluid, molybdenum disulfide lithium-based grease, MP grease, or silicon grease. Also install new bellows, clamps, bushings, and seals. There are certain parts that need to be preloaded; again follow the manufacturer's recommendations. Reassembly is the reverse of the disassembly procedure. Installing a new or rebuilt rack and pinion steering gear follows the opposite procedure as when removing it. Make sure everything is tightened to the torque specified by the manufacturer with the wheels in a straightforward position. Also make sure to check the fluid level when finished and before the vehicle is driven. The vehicle will also need to have its wheels aligned.

Steering Columns

To perform service procedures on the steering column upper end components, it is not necessary to remove the column from the vehicle. The steering wheel, horn components, directional signal switch, ignition switch, and lock cylinder can be removed with the column remaining in the vehicle.

To determine if the energy-absorbing steering column components are functioning as designed, or if repairs are required, a close inspection should be made. An inspection is called for in all cases where damage is evident or whenever the vehicle is being repaired due to a front-end collision. If damage is evident, the affected parts must be replaced. Because of the differences in the steering column styles and various components, consult the service information for more explicit inspection and servicing procedures.

Warning! Set the parking brake before removing the steering column. Also, remove the battery cable from the negative terminal. Remember that special precautions must be observed before beginning disassembly and during assembly to ensure the correct fitting together of the steering column shaft and steering gear shaft connections.

SHOP TALK

On some 4WD vehicles, those with certain cross link steering linkages, the steering wheel must be removed and recentered once the front wheel toe has been set. Refer to the manufacturer's wheel alignment procedures.

Steering Wheels

At times, a customer may complain about an uncentered steering wheel. When the steering wheel is in its centered position, the front wheels should be pointing straight ahead. If the wheels are not in the straight-ahead position, this can be corrected by adjusting the toe of the vehicle. However, this adjustment should only be made if the steering wheel index mark is aligned with the steering column index marks. As a rule, indexing teeth or mating flats on the wheel hub and steering shaft prevent misindexing of these components. One way to verify an incorrectly positioned steering wheel is to turn it from stop to stop and count the number of turns it took. Then take that number and divide it by 2; the result represents the center or straight-ahead position. Now turn the steering wheel to a stop and then the number of turns that represents the center. Look at the front wheels; if they are not in the straight-ahead position, either the steering was installed wrong or the wheels need to have their toe adjusted.

At times the steering wheel must be removed, such as when servicing the multifunctional switch, horn, or the steering column covers. The steering wheel is very unlikely to cause a steering problem.

Warning! The center of the steering wheel contains the driver side air bag. Failure to disarm it can cause serious personal injury.

GO TO Chapter 48 for specific precautions that should be followed when working around or near an air bag.

PROCEDURE

The following is a typical procedure for removing and reinstalling a steering wheel:

To remove:

STEP 1 Place the front wheels facing straight ahead.

STEP 2 Disable the SRS.

STEP 3 Remove the steering pad and air bag.

STEP 4 Remove the steering wheel assembly set nut.

STEP 5 Put alignment marks on the steering wheel and the steering main shaft.

STEP 6 Disconnect the connectors from the spiral cable.

STEP 7 Using the correct puller, remove the steering wheel assembly **(Figure 47–56)**.

To install:

STEP 1 Slip the steering wheel over the main shaft.

STEP 2 Align the alignment marks on the steering wheel assembly and steering main shaft **(Figure 47–57)**.

STEP 3 Install the steering wheel assembly set nut. Torque the nut to specifications.

STEP 4 Connect the connectors to the clockspring (spiral cable) subassembly.

STEP 5 Connect the cable to the negative battery terminal.

STEP 6 Check the SRS warning light.

Power-Steering System Servicing

Vehicles with power-steering systems have the same type of steering linkage as manual steering. The power-steering linkage is checked and serviced as previously described. Actually, the only difference is the servicing of the hydraulic components, such as the hoses, pump, and power-steering gear. One of the common procedures that is recommended by manufacturers as part of a preventive maintenance program is flushing the hydraulic system.

Flushing the System

The reason for flushing the system should be obvious. Hydraulic fluid becomes contaminated by moisture and dirt. Flushing removes the old fluid with its contaminants and new fluid is added to the system. It is also wise to flush the system after you have replaced or repaired a part in the system.

To flush the system, you should disable the engine's ignition. Then disconnect the power-steering return hose and plug the reservoir. Attach an extension hose between the power-steering return hose and an empty container. Raise the vehicle's front wheels off the ground. Fill the reservoir with the correct type of fluid.

Turn the steering wheel from stop to stop while cranking the engine until the fluid leaving the return hose is clean. Never crank the engine for more than 5 seconds at a time. Add fluid to the reservoir to make sure it does not empty. Once the fluid is clear, fill the reservoir to its full mark and lower the vehicle.

Warning! Never mix oil types. Any mixture or any unapproved oil can lead to seal deterioration and leaks.

Disconnect the extension hose from the power-steering return hose and reconnect the return hose to the reservoir. Check the fluid level again and add fluid as necessary. Now enable the ignition system. Start the engine and turn the steering wheel from stop to stop. If the power-steering system is noisy and bubbles are forming in the fluid, the system must be purged of air.

Flushing the system is also commonly performed with the engine running at idle speed. With the return hose placed in a suitable container, start the

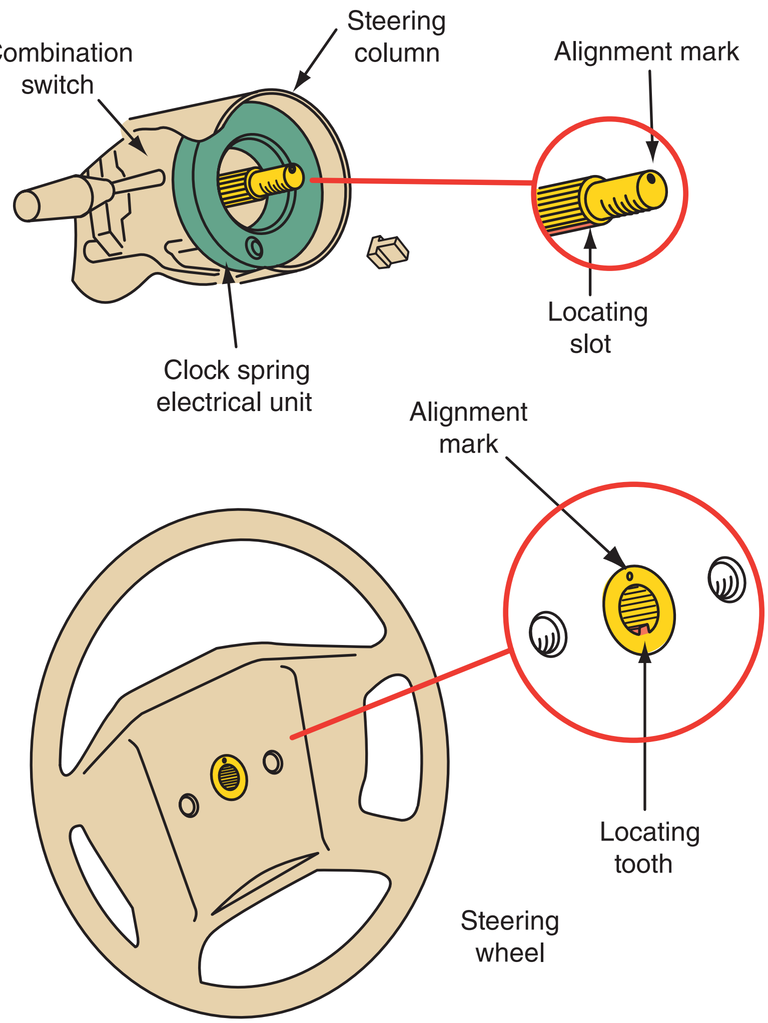

FIGURE 47–57 The steering wheel is splined to the steering column and must be aligned to the reference marks.

engine and turn the steering wheel lock to lock while adding new fluid. Once the fluid coming out of the return hose is new and clean, shut the engine off. Reconnect the return hose and refill the system. Start the engine and bleed any air from the system.

Bleeding the System

Often the procedure for bleeding the power-steering system is called "purging" the system, because it moves air that may be trapped in the fluid. Purging the system must be done after the replacement of any part of the power-steering hydraulic system or when there is a problem that indicates there may be aerated fluid, such as a whining noise.

The method for bleeding the system depends on the type of power steering the vehicle is equipped with. Follow the procedures given in the service information. If the system is not purged correctly or if air is allowed to remain in the system, the power-steering pump can fail prematurely. What follows is a typical procedure.

Electric Power-Steering Systems

When working on a vehicle with EPS, remember that the electric motor adds the assist. It must be positioned properly in order to provide assist equally to both sides. Therefore, it is important that the front wheels are in their straight-ahead position whenever any part of the steering linkage is removed or installed. If it is necessary to disconnect the steering column shaft from the steering gear, mark the alignment of the two before disconnecting it. When reattaching the shaft, make sure the marks are aligned.

Electric power assist systems use steering angle sensors or a torque sensor to help determine how much power assist to provide. A torsion bar links the input shaft from the steering column to the pinion in the steering gear. The torsion bar twists in response to the movement of the steering wheel. The torque sensor typically has two sensors or resolvers that detect the twist of the torsion bar. One sensor is on the input side of the shaft and another is on the output side. The difference in movement between the input and

PROCEDURE

Follow these steps to bleed a power-steering hydraulic system:

STEP 1 Remove the reservoir cap.

STEP 2 Tightly install the adapter of the vacuum pump to the reservoir opening.

STEP 3 Start the engine.

STEP 4 Connect the vacuum pump.

STEP 5 Apply 20 to 25 in. Hg (68 to 85 kPa) of vacuum. Note: If the vehicle has a hydro-boost system, depress the brake pedal two times.

STEP 6 Fully cycle the steering wheel from stop to stop ten times.

STEP 7 Turn off the engine.

STEP 8 Release the vacuum and remove the adapter from the reservoir.

STEP 9 Fill the reservoir with the correct fluid.

STEP 10 Tightly install the adapter of the vacuum pump to the reservoir opening.

STEP 11 Start the engine.

STEP 12 Apply 20 to 25 in. Hg (68 to 85 kPa) of vacuum. Note: If the vehicle has a hydro-boost system, depress the brake pedal two times.

STEP 13 Turn off the engine.

STEP 14 Release the vacuum and remove the adapter from the reservoir.

STEP 15 Fill the reservoir with the correct fluid.

output sensors is used to determine steering torque. Both steering angle and torque sensors must be recalibrated whenever the steering gear, steering wheel, steering column, or steering control module has been removed or replaced. Recalibration is also needed after setting the front wheel alignment or if there is a difference in steering effort when turning right or left. Follow the manufacturer's directions for calibrating this sensor. In general, there are three methods for sensor calibration:

- Self-calibrating—meaning the system will relearn on its own after turning the steering wheel from lock-to-lock.

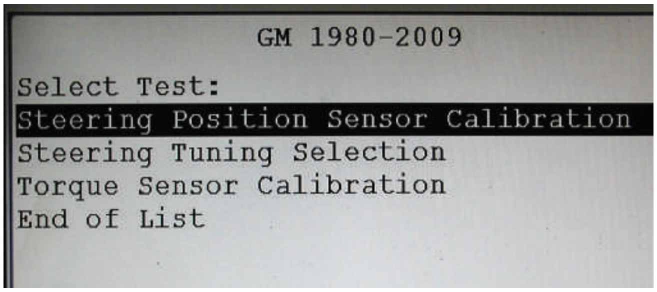

FIGURE 47–58 The electric power steering calibrations on a GM vehicle.

- Toyota/Lexus—using a jumper wire to short specific terminals together at the data link connector.
- Scan tool relearn—many vehicles using either a scan tool or the software with the alignment machine to perform a relearn **(Figure 47–58)**.

If the sensor is faulty, steering effort in both directions may increase or the steering wheel may not return properly.

Hoses and Lines

Hoses and lines should also be carefully inspected for leaks, dents, sharp bends, cracks, and swelling. Always replace the power-steering hoses with an exact replacement hose. Never attempt to patch or seal a leak in a hose or the hose's fittings. Lines and hoses must not rub against other components. This can wear a hole in the line or hose. Many high-pressure lines are made of high-pressure steel-braided hose with molded steel fittings on each end.

Power-Steering Pump

To replace a power-steering pump follow the manufacturer's service procedures. Begin by removing the drive belt. Next, determine if the pulley must be removed to remove the pump from its bracket. If so, remove the pulley using the appropriate puller. Remove the return hose and drain the power steering fluid into an oil pan, then remove the pressure hose. Next, unbolt the pump from the bracket and remove the pump. Compare the old pump to the replacement pump. Make sure the replacement pump has the same size fitting and mounting points. Install the new pump and torque the fasteners to specifications. Reconnect the hoses and reinstall the pulley and drive belt. Fill the system with the correct power steering fluid and bleed the air from the system. Start the engine, check for leaks, and ensure proper power steering operation.

Although power-steering pumps are not typically rebuilt by technicians, some parts are replaceable.

PROCEDURE

When power steering hose replacement is required, follow these steps:

STEP 1 With the engine stopped, remove the return hose at the power-steering gear, and allow the fluid to drain into a drain pan.

STEP 2 Loosen and remove all hose fittings from the pump and steering gear.

STEP 3 Remove all hose-to-chassis clips.

STEP 4 Remove the hoses from the chassis, and cap the pump and steering gear fittings.

STEP 5 If O-rings are used on the hose ends, install new O-rings. Some lines have gaskets. The old gasket must be pried out of the fitting before installing the new lines. Lubricate the O-rings with power-steering fluid.

STEP 6 Install the new hose by reversing the steps for removal. Make sure to tighten all fittings to the specified torque. Be sure all hose-to-chassis clips are in place. Do not position hoses where they rub on other components.

STEP 7 Fill the pump reservoir to the full mark with the manufacturer's recommended fluid. Bleed air from the power-steering system, then check the fluid level in the reservoir and add fluid as required.

The actual parts that can be replaced depend on the make of the pump. The common parts that can be replaced are discussed next.

Power-Steering Pump Pulley Replacement If the pulley wobbles while it is rotating, it is undoubtedly bent and should be replaced. Worn pulley grooves and/or cracks also indicate that the pulley should be replaced. A pulley that is loose on the pump's shaft must be replaced. Never hammer on the pump's drive shaft during pulley removal or installation. This will damage the internal parts of the pump.

If the pulley is pressed onto the pump's shaft, a special puller **(Figure 47–59A)** is required to remove it and a pulley installation tool is used to install the pulley **(Figure 47–59B)**. When replacing a pump, the replacement pump usually does not come with a pulley. You will need to remove the pulley from the old pump and reinstall it on the new pump.

To remove the pulley, install the puller over the lip of the pulley and tighten the puller bolt against the pump's driveshaft. Hold the body of the puller with a wrench and tighten the puller bolt. This will pull the pulley from the pump shaft. To reinstall, align the pulley onto the pump shaft and thread the installation bolt into the driveshaft. Tighten the bolt and hold it from turning with a wrench or socket. Using a wrench, tighten the nut against the pulley. This will push the pulley onto the driveshaft. Once the pulley is seated in place, spin the pulley to make sure it does not wobble. A bent pulley should be replaced since it will cause premature belt wear.

PROCEDURE

Remove and Replace the Pressure Relief Valve

Follow this procedure to service the pressure relief valve:

1. Wrap a shop towel around the land end of the flow control valve and clamp this end in a soft-jawed vise. Be very careful not to damage the valve lands.
2. Remove the hex-head ball seat. Clean the components in solvent. A worn or damaged pressure relief ball, spring, guide, or seat must be replaced.
3. Reinstall the new or cleaned components, and then install the ball seat.

If the power-steering pump pulley is retained with a nut, mount the pump in a vise. Always tighten the vise on one of the pump's mounting bolt surfaces. Do not tighten the vise with excessive force. Use a special holding tool to keep the pulley from turning, and loosen the nut with a box-end wrench. Remove the nut, pulley, and woodruff key. Inspect the pulley, shaft, and woodruff key for wear. Replace all worn components.

Remove and Replace the Flow Control Valve and End Cover To replace the flow control valve and end plate, remove the retaining ring with a slotted screwdriver and punch. Then remove the flow control valve, end cover, spring, and magnet. Check the flow control valve for burrs. Remove minor burrs with crocus cloth, and clean the flow control valve in solvent. Damaged or worn flow control valves must be replaced. Inspect the end cover sealing surface for damage. Also check the pump's drive shaft for corrosion and damage. Remove any corrosion with crocus cloth. Clean all parts and lubricate the end cover with power-steering fluid. Make sure to clean the magnet with a shop towel. To reassemble, install the flow control valve, end cover, retaining ring, and related components.

Four-Wheel Steering Systems

A few manufacturers have offered four-wheel steering systems in which the rear wheels also help to turn the car by electrical, hydraulic, or mechanical means. Although they certainly are not very common, you should be aware of how they work.

Production-built cars tend to understeer or, in a few instances, oversteer. Understeer is when the vehicle cannot follow a turn due to the front wheels losing traction. Trying to turn too fast on a slippery road and sliding through an intersection is an example of understeer. Oversteer occurs with the vehicle turns more than is needed, typically due to the back wheels losing traction and breaking loose. If a car could automatically compensate for an understeer/oversteer problem, the driver would enjoy nearly neutral steering under varying operating conditions. Four-wheel steering (4WS) is a serious effort on the part of automotive design engineers to provide near-neutral steering with the following advantages:

- The vehicle's cornering behavior becomes more stable and controllable at high speeds as well as on wet or slippery road surfaces **(Figure 47–60)**.
- The vehicle's response to steering input becomes quicker and more precise throughout the vehicle's entire speed range.
- The vehicle's straight-line stability at high speeds is improved. Negative effects of road irregularities and crosswinds on the vehicle's stability are minimized.
- Stability in lane changing at high speeds is improved. High-speed slalom-type operations become easier. The vehicle is less likely to go into a spin even in situations in which the driver must make a sudden and relatively large change of direction.
- By steering the rear wheels in the direction opposite the front wheels at low speeds, the vehicle's turning circle is greatly reduced. Therefore, vehicle maneuvering on narrow roads and during parking becomes easier.

To understand the advantages of four-wheel steering, it is wise to review the dynamics of typical steering maneuvers with a conventional front-steered

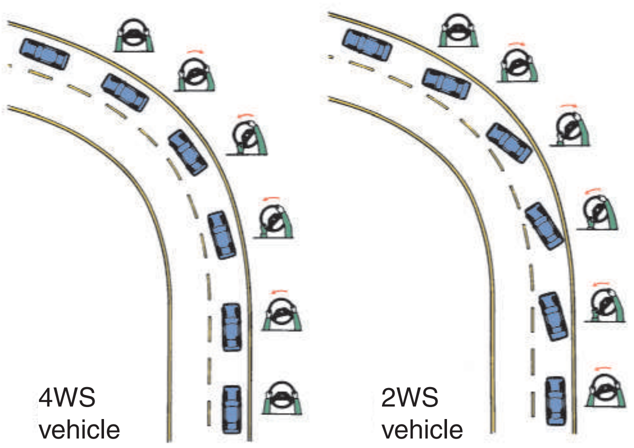

FIGURE 47–60 A comparison of 2WS and 4WS vehicle behavior during cornering.

vehicle. The tires are subject to the forces of grip, momentum, and steering input when making a movement other than straight-ahead driving. These forces compete with each other during steering maneuvers. With a front-steered vehicle, the rear end is always trying to catch up to the directional changes of the front wheels. This causes the vehicle to sway. As a normal part of operating a vehicle, the driver learns to adjust to these forces without thinking about them.

When turning, the driver is putting into motion a complex series of forces. Each of these must be balanced against the others. The tires are subjected to road grip and slip angle. Grip holds the car's wheels to the road, and momentum moves the car straight ahead. Steering input causes the front wheels to turn. The car momentarily resists the turning motion, causing a tire slip angle to form. Once the vehicle begins to respond to the steering input, cornering forces are generated. The vehicle sways as the rear wheels attempt to keep up with the cornering forces already generated by the front tires. This is referred to as rear-end lag because there is a time delay between steering input and vehicle reaction. When the front wheels are turned back to a straight-ahead position, the vehicle must again try to adjust by reversing the same forces developed by the turn. As the steering is turned, the vehicle body sways as the rear wheels again try to keep up with the cornering forces generated by the front wheels.

The idea behind four-wheel steering is that a vehicle requires less driver input for any steering maneuver if all four wheels are steering the vehicle. As with two-wheel-steer vehicles, tire grip holds the four wheels on the road. However, when the driver turns the wheel slightly, all four wheels react to the steering input, causing slip angles to form at all four wheels. The entire vehicle moves in one direction rather than the rear half attempting to catch up to the front. There is also less sway when the wheels are turned back to a straight-ahead position. The vehicle responds more quickly to steering input because rear wheel lag is eliminated.

Because each 4WS system is unique in its construction and repair needs, the vehicle's service information must be followed for proper diagnosis, repair, and alignment of a four-wheel system.

Mechanical 4WS

In a straight-mechanical type of 4WS, two steering gears are used—one for the front and the other for the rear wheels. A steel shaft connects the two steering gearboxes and terminates at an eccentric shaft that is fitted with an offset pin **(Figure 47–61)**. This pin engages a second offset pin that fits into a planetary gear.

The planetary gear meshes with the matching teeth of an internal gear that is secured in a fixed position to the gearbox housing. This means that the planetary gear can rotate but the internal gear cannot. The eccentric pin of the planetary gear fits into a hole in a slider for the steering gear.

A 120-degree turn of the steering wheel rotates the planetary gear to move the slider in the same direction that the front wheels are headed. Proportionately, the rear wheels turn about 1.5 to 120 degrees of the steering wheel. Further rotation of the steering wheel, past the 120-degree point, causes the rear wheels to start straightening out due to the double-crank action (two eccentric pins) and rotation of the planetary gear. Turning the steering wheel to a greater angle, about 230 degrees, finds the rear wheels in a neutral position regarding the front wheels. Further rotation of the steering wheel, at about 450 degrees, results in the rear wheels going counter phase with regard to the front

wheels. About 5.3 degrees maximum counterphase rear steering is possible.

Mechanical 4WS is steering angle sensitive. It is not sensitive to vehicle road speed.

Hydraulic 4WS

The hydraulically operated 4WS system shown in **Figure 47–62** is a simple design, both in components and operation. The rear wheels turn only in the same direction as the front wheels. They also turn no more than 1½ degrees. The system only activates at speeds above 30 mph (50 kph) and does not operate when the vehicle moves in reverse.

A two-way hydraulic cylinder mounted on the rear stub frame turns the wheels. Fluid for this cylinder is supplied by a rear steering pump that is driven by the differential. The pump only operates when the front wheels are turning. A tank in the engine compartment supplies the rear steering pump with fluid.

When the steering wheel is turned, the front steering pump sends fluid under pressure to the rotary valve in the front rack and pinion unit. This forces fluid into the front power cylinder, and the front wheels turn in the direction steered. The fluid pressure varies with the turning of the steering wheel. The faster and farther the steering wheel is turned, the greater the fluid pressure.

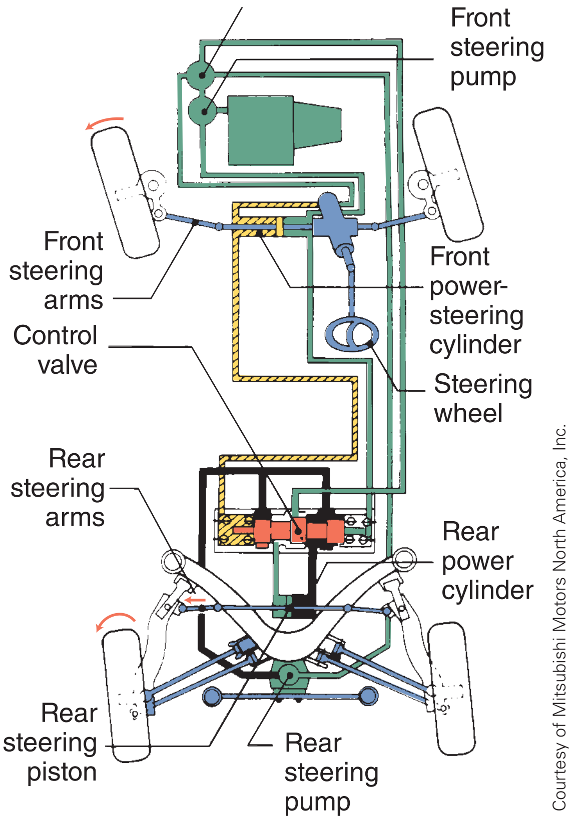

FIGURE 47–62 A simple hydraulic 4WS system.

The fluid is also fed under the same pressure to the control valve, where it opens a spool valve in the control valve housing. As the spool valve moves, it allows fluid from the rear steering pump to move through and operate the rear power cylinder. The higher the pressure on the spool, the farther it moves. The farther it moves, the more fluid it allows through to move the rear wheels. As mentioned earlier, this system limits rear wheel movement to 1½ degrees in either the left or right direction.

Electrohydraulic 4WS

Several 4WS systems combine computer electronic controls with hydraulics to make the system sensitive to both steering angle and road speeds. In this design, a speed sensor and steering wheel angle sensor feed information to the electronic control unit (ECU). By processing the information received, the ECU commands the hydraulic system to steer the rear wheels. At low road speed, the rear wheels of this system are not considered a dynamic factor in the steering process.

At moderate road speeds, the rear wheels are steered momentarily counterphase, through neutral, then in phase with the front wheels. At high road speeds, the rear wheels turn only in phase with the front wheels. The ECU must know not only road speed, but also how much and how quickly the steering wheel is turned. These three factors—road speed, amount of steering wheel turn, and the quickness of the steering wheel turn—are interpreted by the ECU to maintain continuous and desired steering angle of the rear wheels.

Another electrohydraulic 4WS system is shown in **Figure 47–63**. The basic working elements of the design are the control unit, a stepper motor, a swing arm, a set of beveled gears, a control rod, and a control valve with an output rod. Two electronic sensors tell the ECU how fast the car is going.

The yoke is a major mechanical component of this electrohydraulic design. The position of the control yoke varies with vehicle road speed. For example, at speeds below 33 mph (53 km/h), the yoke is in its downward position, which results in the rear wheels steering in the counterphase (opposite front wheels) direction. As road speeds approach and exceed 22 mph (35 km/h), the control yoke swings up through a neutral (horizontal) position to an up position. In the neutral position, the rear wheels steer in phase with the front wheels.

The stepper motor moves the control yoke. A swing arm is attached to the control yoke. The position of the yoke determines the arc of the swing rod. The arc of the swing arm is transmitted through a control arm that passes through a large bevel gear. Stepper motor action eventually causes a push-or-pull

movement of its output shaft to steer the rear wheels up to a maximum of 5 degrees in either direction.

The electronically controlled 4WS system regulates the angle and direction of the rear wheels in response to speed and driver's steering. This speed-sensing system optimizes the vehicle's dynamic characteristics at any speed, thereby producing enhanced stability and, within certain parameters, agility.

The actual 4WS system consists of a rack and pinion front steering that is hydraulically powered by a main twin-tandem pump. The system also has a rear-steering mechanism, hydraulically powered by the main pump. The rear-steering shaft extends from the rack bar of the front-steering assembly to the rear-steering-phase control unit.

The rear steering is comprised of the input end of the rear-steering shaft, vehicle speed sensors, and steering-phase control unit (deciding direction and degree), a power cylinder, and an output rod. A centering lock spring is incorporated that locks the rear system in a neutral (straight-ahead) position in the event of hydraulic failure. Additionally, a solenoid valve that disengages the hydraulic boost (thereby activating the centering lock spring in case of an electrical failure) is included.

All 4WS systems have fail-safe measures. For example, with the electrohydraulic setup, the system automatically counteracts possible causes of failure, both electronic and hydraulic, and converts the entire steering system to a conventional two-wheel steering type. Specifically, if a hydraulic defect should reduce pressure level (by a movement malfunction or a broken driving belt), the rear-wheel-steering mechanism is automatically locked in a neutral position, activating a low-level warning light.

An electrical failure would be detected by a self-diagnostic circuit integrated in the four-wheel-steering control unit. The control unit stimulates a solenoid valve, which neutralizes hydraulic pressure, thereby alternating the system to two-wheel steering. The failure would be indicated by the system's warning light in the main instrument display.

On any 4WS system, there must be near-perfect compliance between the position of the steering wheel,

the position of the front wheels, and the position of the rear wheels. It is usually recommended that the car be driven about 20 feet (6 meters) in a dead-straight line. Then, the position of the front/rear wheels is checked with respect to steering wheel position. The base reference point is a strip of masking tape on the steering wheel hub and the steering column. When the wheel is positioned dead center, draw a line down the tape. Run the car a short distance straight ahead to see if the reference line holds. If not, corrections are needed, such as repositioning the steering wheel.

Even severe imbalance of a rear wheel on a speed-sensitive 4WS system can cause problems and make basic troubleshooting a bit frustrating.

Quadrasteer

Quadrasteer was a 4WS system that was an option on GM's full-size pickup and model 2500 Suburbans during the model years 2002 through 2005. This system improved low-speed maneuverability, high-speed stability, and trailering capabilities for full-size pickups, vans, and SUVs. The system combined normal front-wheel steering with an electrically powered and electronically controlled rear-wheel steering system. The system was primarily controlled by vehicle speed sensors and a central control module **(Figure 47–64)**.

At low speeds, the rear wheels turned in the opposite direction as the front wheels **(Figure 47–65)**.

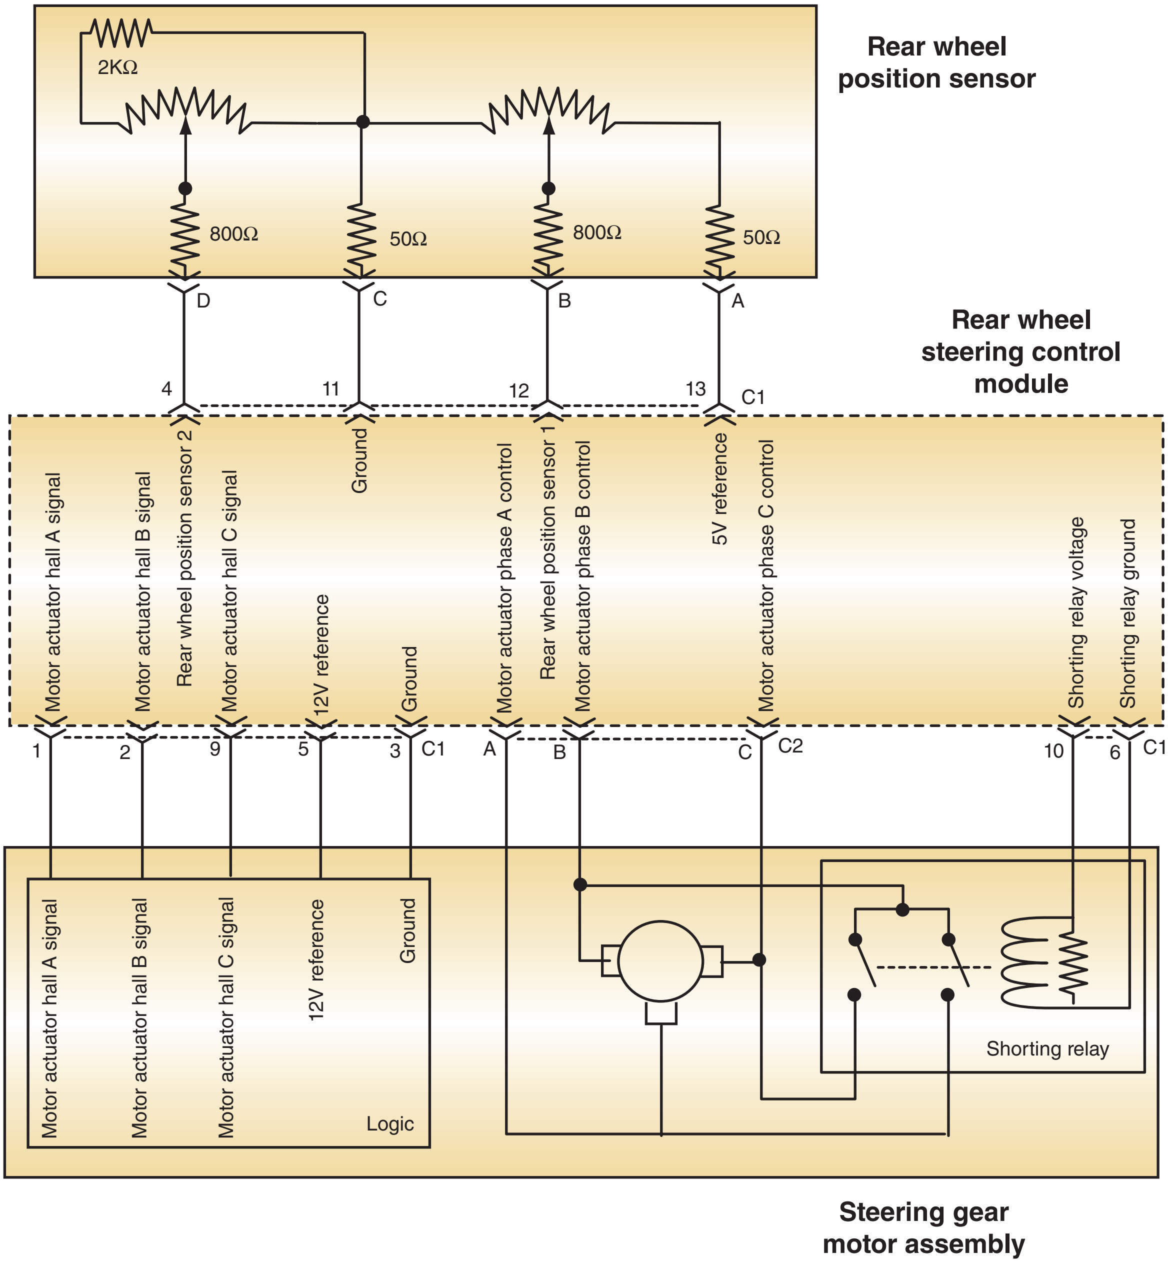

FIGURE 47–64 The components controlling the four-wheel steering system.

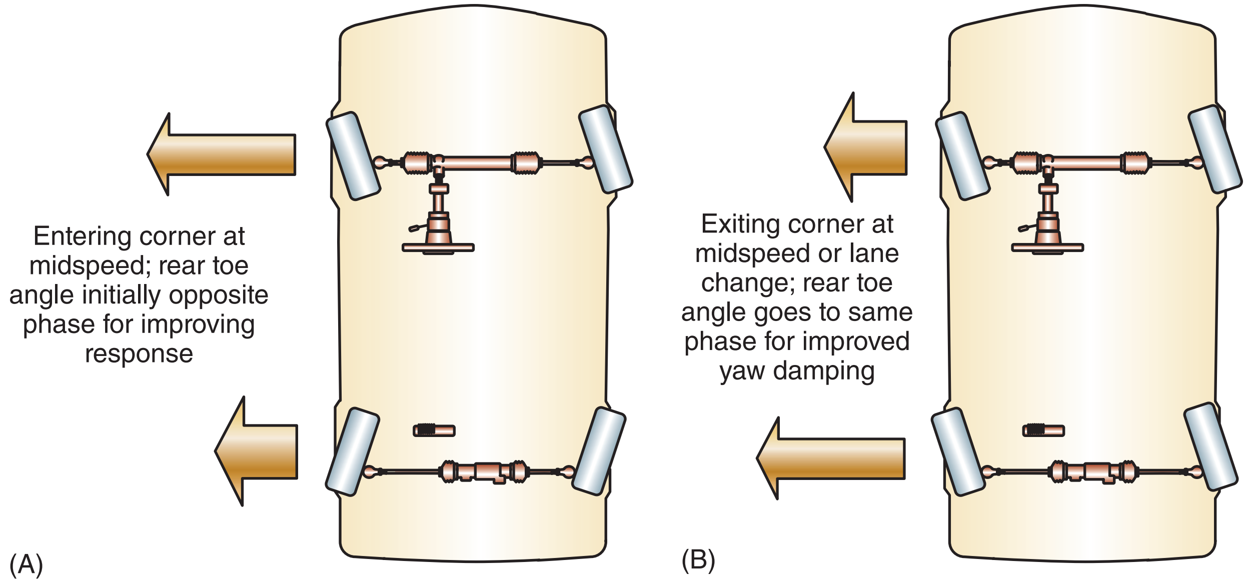

FIGURE 47–65 The different operational modes of a Quadrasteer system. Counter-steering at low speeds (A) and in-phase or following steering at higher speeds (B).

At moderate speeds, the rear wheels remained straight. At high speeds, the rear wheels turned in the same direction as the front wheels. If the system failed, the truck defaulted to normal two-wheel steering.

Acura Precision All-Wheel Steer

The Acura Precision All-Wheel Steer (P-AWS) system introduced in 2015 was their first system capable of independently adjusting the toe angle of the rear wheels. The system relies on two electric actuators, one for each rear wheel **(Figure 47–66)**. The actuators can change rear tire angle up to 1.8 degrees. During low speed operation, the wheels are reverse- or counterphase, pointing in the opposite direction of the front tires to improve turning radius. At higher speeds, the rear wheels turn with the front wheels to allow quick lane changes. During high-speed cornering, the rear wheels reverse-phase to help the car through the turn. Under high-speed braking, both rear wheels toe-in to increase braking stability.

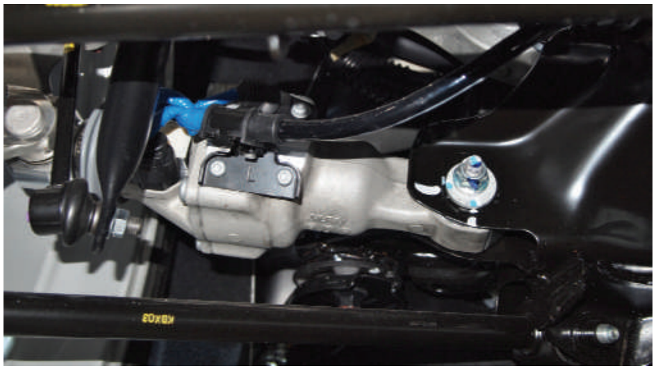

FIGURE 47–66 Acura's 4WS system uses two electric actuators, one for each rear wheel.

Active Rear Axle Steering

ZF Friedrichshafen AG, also known as the ZF Group, has developed a 4WS system that is used by a few European manufacturers, such as Porsche, Audi, BMW, Mercedes-AMG, and Lamborghini. Porsche models, for example, use two different variations of this rear axle steering system. Basically the system relies on an electric motor that is controlled by a control module. The module receives inputs from a variety of sensors that monitor the current operating conditions, including the direction of the front wheels and vehicle speed. This is why it is called an active system. These are pure "by-wire" systems, there is no mechanical connection between the steering wheel and the motors.

One variation of the system relies on two small electromechanical actuators that change the rear wheel's toe angle. This system is used on the rear-engine RWD 911. With this dual-actuator system, each wheel is individually steered by a separate

actuator **(Figure 47–67)**. The motors inside the actuator assembly move each wheel slightly to the right or the left. The motors drive a belt that in turn drives a gear, which moves a tie rod attached to each wheel's spindle.

The other system, called a central actuator system is used in Porsche's Panamera. This system has one motor installed in the center of the rear axle which simultaneously turns both wheels by moving a tie rod attached to each wheel's spindle. The ultimate goal of this system is the same as the dual actuator system and most other 4WS systems.

SUMMARY

- The components of a manual-steering system include the steering linkage, steering gear, and the steering column and wheel.
- The term *steering linkage* is applied to the system of pivots and connecting parts placed between the steering gear and the steering arms that are attached to the front wheels, controlling the direction of vehicle travel. The steering linkage transfers the motion of the steering gear output shaft to the steering arms, turning the wheels to maneuver the vehicle.
- Basic components of a parallelogram steering linkage system include the Pitman arm, idler arm, links, tie-rods, and, in some designs, a steering damper.
- The worm and roller steering components are basically the same as found in the parallelogram system.
- In rack and pinion steering linkage, steering input is received from a pinion gear attached to the steering column. This gear moves a toothed rack that is attached to the tie-rods that move the wheels.
- There are three types of manual steering gears in use today: recirculating ball, worm and roller, and rack and pinion.
- The steering wheel and column produce the necessary force to turn the steering gear.
- The power-steering unit is designed to reduce the amount of effort required to turn the steering wheel. It also reduces driver fatigue on long drives and makes it easier to steer the vehicle at slow road speeds, particularly during parking.
- There are several power-steering systems in use on passenger cars and light-duty trucks. The

most common ones are the integral, linkage, hydro-boost, and power-assisted rack and pinion systems.

- The major components of a conventional power-steering system are the steering linkage, power-steering pump, flow control and pressure relief valves, reservoir, spool valves and power pistons, hydraulic hose lines, and gearbox or assist assembly on the linkage.
- Electronic rack and pinion systems replace the hydraulic pump, hoses, and fluid associated with conventional power-steering systems with electronic controls and an electric motor located concentric to the rack itself.
- Four-wheel steering (4WS) advantages include cornering capability, steering response, straight-line stability, lane changing, and low-speed maneuverability.

RESTRAINT SYSTEMS: THEORY, DIAGNOSIS, AND SERVICE

OBJECTIVES

- Explain the difference between active and passive restraint systems.
- Know how to service and repair passive belt systems.
- Describe the function and operation of air bags.
- Identify the major parts of a typical air bag system.
- Safely disable and inspect an air bag assembly.
- Know how to diagnose and service an air bag system.
- Diagnose faults with restraint systems.

Safety is foremost in the minds of automobile manufacturers. According to a survey by the Insurance Institute for Highway Safety, occupant protection has emerged as a leading factor in determining which car people will buy. According to the institute, 68 percent of the households surveyed ranked the "degree to which the car protects people" as a very important purchase-decision factor.

Many safety features are now available as standard equipment or as options. Some of these standard features include side impact barriers, crumple zones in the body, seat belts, antilock brakes, traction control, stability control, and air bags **(Figure 48–1)**. There are many safety items that have been around for many years, such as laminated and tempered glass.

Common restraint systems—seat belts and air bags—are covered in this chapter. It is important for a technician to understand how

these systems work and how to diagnose and service them.

An **active restraint system** is one that a vehicle's occupant must make a manual effort to use **(Figure 48–2)**. For example, in most vehicles the passenger must fasten the seat belts for crash protection. A passive restraint system operates automatically **(Figure 48–3)**. No action is required of the occupant to make it functional.

Passive safety equipment includes the safety belt system, the air bags, the rigid occupant cell, and the crumple zones at the front of the vehicle. The rear and sides of the body are among the most important safety features of today's cars and are designed to dissipate most of the impact energy for the protection of vehicle occupants.

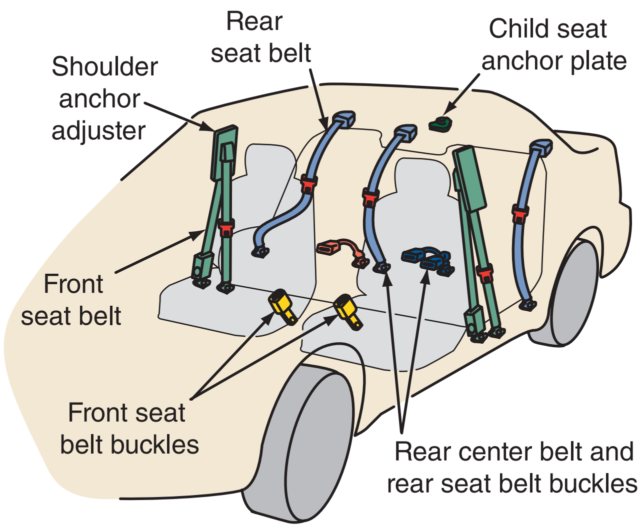

FIGURE 48–2 An active restraint system.

Seat Belts

A passive seat belt system uses electric motors to automatically move shoulder belts across the driver and front seat passenger. The upper end of the belt is attached to a carrier that moves in a track at the top of the doorframe. The other end is secured to an inertia lock retractor mounted to the center console. When the door is opened, the outer end of the shoulder belt moves forward to allow for easy entry or exit. When the doors are closed and the ignition is turned on, the belts move rearward and secure the occupants. The active lap belt is manually fastened and should be worn with the passive belt.

Most vehicles have two active belts. One is a lap belt that goes across the occupant's lap; the other is a shoulder belt that goes across the shoulder and chest. The two belts join together at a single point where they are inserted into a buckle anchored to the vehicle's floor.

If a seat belt will not buckle, use a flashlight and look inside the buckle. Often something is inside the buckle that can be safely removed. It does not take much to hamper the operation of the buckle. In most cases, the buckle should be replaced if something is lodged inside.

Seat Belt Retractors

When unbuckled, seat belts are stowed away by the seat belt retractors **(Figure 48–4)**. The retractors may also work as pretensioners to take up the belt's slack during an accident to limit the forward movement of the occupant's body. Inertia lock retractors **(Figure 48–5)** prevent the belt from coming out of the retractor when there is a sudden pull on the belt. Some vehicles have electric or pyrotechnic-type pretensioners. Both of these are designed to quickly tighten the belt at the start of a crash.

Pyrotechnic pretensioners are the most common **(Figure 48–6)**. When the pretensioner receives a signal from the control module, the pretensioner is ignited. There is a small explosion in the pretensioner that reverses its action. This puts a firm hold on the passenger. Many of these systems also

have a mechanism that releases the pressure on the seat belt after it has been tightened by the pretensioner. When the pressure between the passenger's chest and the seat belt exceeds a particular point, the pressure on the seat belt is relaxed to prevent injury.

On some vehicles, the action of the pretensioners varies with the weight of the person in the seat and the amount of force on the seat belt as that person is moving forward during an impact. Some vehicles are equipped with two-stage belt force limiters.

FIGURE 48–6 A buckle-mounted pretensioner.

Warning Lights

All modern seat belt systems have a warning lamp and a buzzer or chime that is turned on when the vehicle is started to remind the occupants to buckle up. When the ignition is turned on, a signal is sent to the warning lamp **(Figure 48–7)**. If the seat belt is fastened, a signal is sent from the buckle switch to the indicator controller and the lamp turns off. If the belt is not buckled, the indicator and buzzer will alert the driver in intervals. There is a sensor in the front passenger seat that detects when someone is in the seat. This information is sent to the control module and the indicator lamp will blink until the seat belt is fastened.

Seat Belt Service

Inspecting seat belt systems should follow a systematic approach. Always take as much time as necessary to do your inspection. Remember that seat belts are designed to protect people.

Webbing Inspection

Pay special attention to where the webbing contacts maximum stress points, such as the buckle, D-ring,

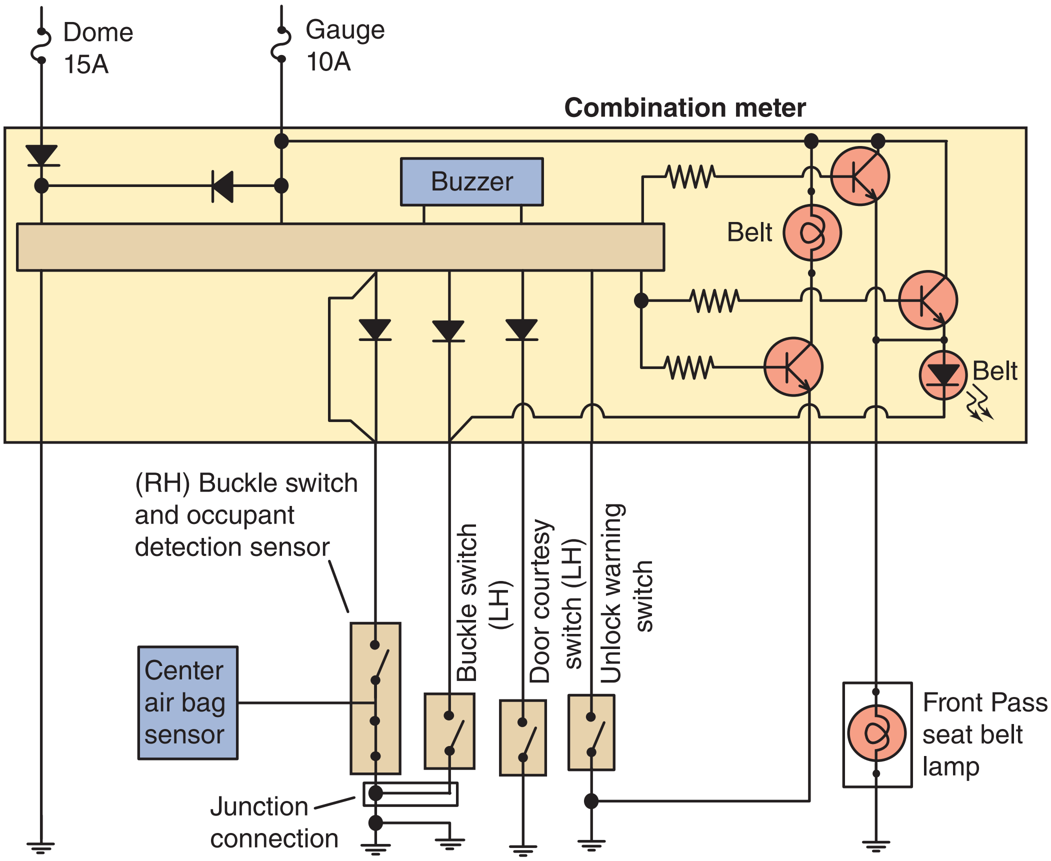

FIGURE 48–7 A wiring diagram for the seat belt warning and key reminder indicators.

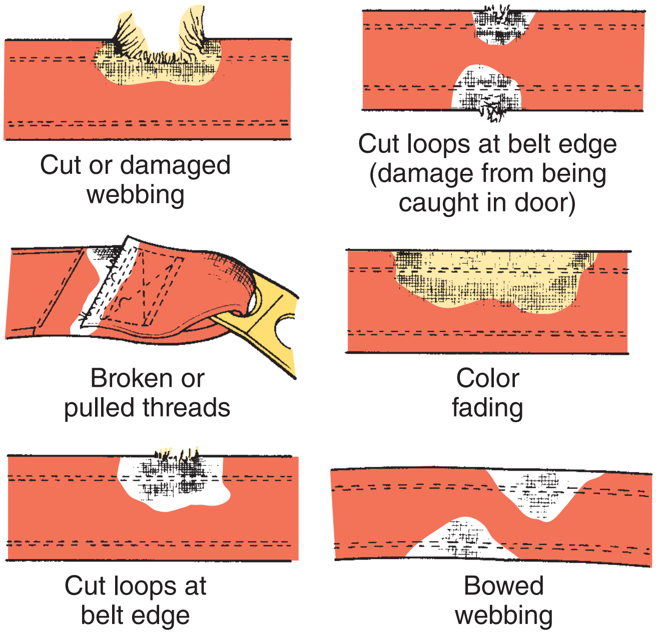

FIGURE 48–8 Examples of webbing defects.

and retractor. Collision forces center on these locations and can weaken the belt. Signs of damage at these points require belt replacement. Check for twisted webbing due to improper alignment when connecting the buckle. Fully extend the webbing from the retractor. Inspect the webbing and replace it with a new assembly if the following conditions are noted **(Figure 48–8)**: cut or damaged webbing, broken or pulled threads, cut loops at the belt edge, color fading as a result of exposure to sun or chemical agents, or bowed webbing.

If the webbing cannot be pulled out of the retractor or will not retract to the stowed position, check for the following conditions and clean or correct as necessary: webbing soiled with gum, syrup, grease, or other material; twisted webbing; or the retractor or loop on the B-pillar out of position.

Buckle Inspection

To determine if the buckle works or if the buckle housing has been damaged, insert the seat belt into the buckle until a click is heard. Pull back on the webbing quickly to ensure that the buckle is latched properly. Replace the seat belt assembly if the buckle does not latch. Depress the button on the buckle to release the belt. The belt should release with a pressure of approximately 2 pounds. Replace the seat belt assembly if the buckle cover is cracked, the push button is loose, or the pressure required to release the button is too high.

Retractor Inspection

Retractors for lap belts should lock automatically once the belt is fully out. Either webbing-sensitive or vehicle-sensitive seat belt retractors are used with passive seat belt systems. Webbing-sensitive retractors can be tested by grasping the seat belt and jerking it. The retractor should lock up; if it does not, replace the seat belt retractor.

Vehicle-sensitive belt retractors will not lock up using the same procedure. To test these belts, a braking test is required. Perform this test in a safe place. A helper is required to check the retractors on the passenger side and in the back if the vehicle is equipped with rear lap/shoulder belts.

Test each belt by driving the car at 5 to 8 mph and quickly applying the brakes. If a belt does not lock up, replace the seat belt assembly. During this test, it is important for the driver and helper to brace themselves in the event the retractor does not lock up.

Most retractors are not interchangeable. That is, an R marked on the retractor tab indicates that it is for the right side only, and an L should be used on the left side only.

Anchor Inspection

Carefully inspect the anchor areas and attaching bolts for the retractors. A buildup of dirt in the anchors can cause the seat belts to retract slowly. Wipe the inside of the loops with a clean cloth dampened in isopropyl alcohol. Loose bolts should be replaced and the new bolts tightened to specifications. Look for cracks and distortion in the metal at the anchor points. If there is damage to the metal in the mounting area, proper repairs, such as welding in reinforcement metal, must be completed before reattaching the anchor. Be sure to restore corrosion protection to the area. When spraying anticorrosion materials, make sure they do not enter the retractor. This can keep it from operating properly. Finally, look for dirt and corrosion around the anchor area.

Pretensioners should be replaced if a collision caused the air bags to deploy. They are explosive devices and good for one-time use.

SHOP TALK Never bleach or dye the belt webbing. Clean it with a mild soap solution and water.

Caution! Never measure the resistance of a seat belt pretensioner. The voltage from the meter may accidentally ignite the pretensioner. This can result in serious personal injury.

Drive Track Assembly

Passive systems have a drive motor usually located at the base of the track assembly behind the rear seat side trim panel. The motor pulls the tape that positions the belt. If the motor is faulty, replace it. To service a motorized seat belt system, follow the instructions given in the service information.

Rear Seat Restraint System

Rear seat belts are inspected in the same way as the front. However, some vehicles have a center seat belt. These belts do not have a retractor. Check the webbing, anchors, and the adjustable locking slide for the belt. Fasten the tongue to the buckle and adjust by pulling the webbing end at a right angle to the connector and buckle. Release the webbing and pull upward on the connector and buckle. If the slide lock does not hold, remove and replace that seat belt assembly.

Warning Light and Sound Systems

When the ignition is turned to the on or run position, the Fasten Seat Belt light should come on. There should also be a buzzer or chime. If these warning light and sound systems do not come on, check for a blown fuse or circuit breaker. If that checks out fine, and there is sound but no light, check for a damaged or burned-out bulb. If the bulb lights but there is no sound, check for damaged or loose wiring, switches, or buzzer (voice module).

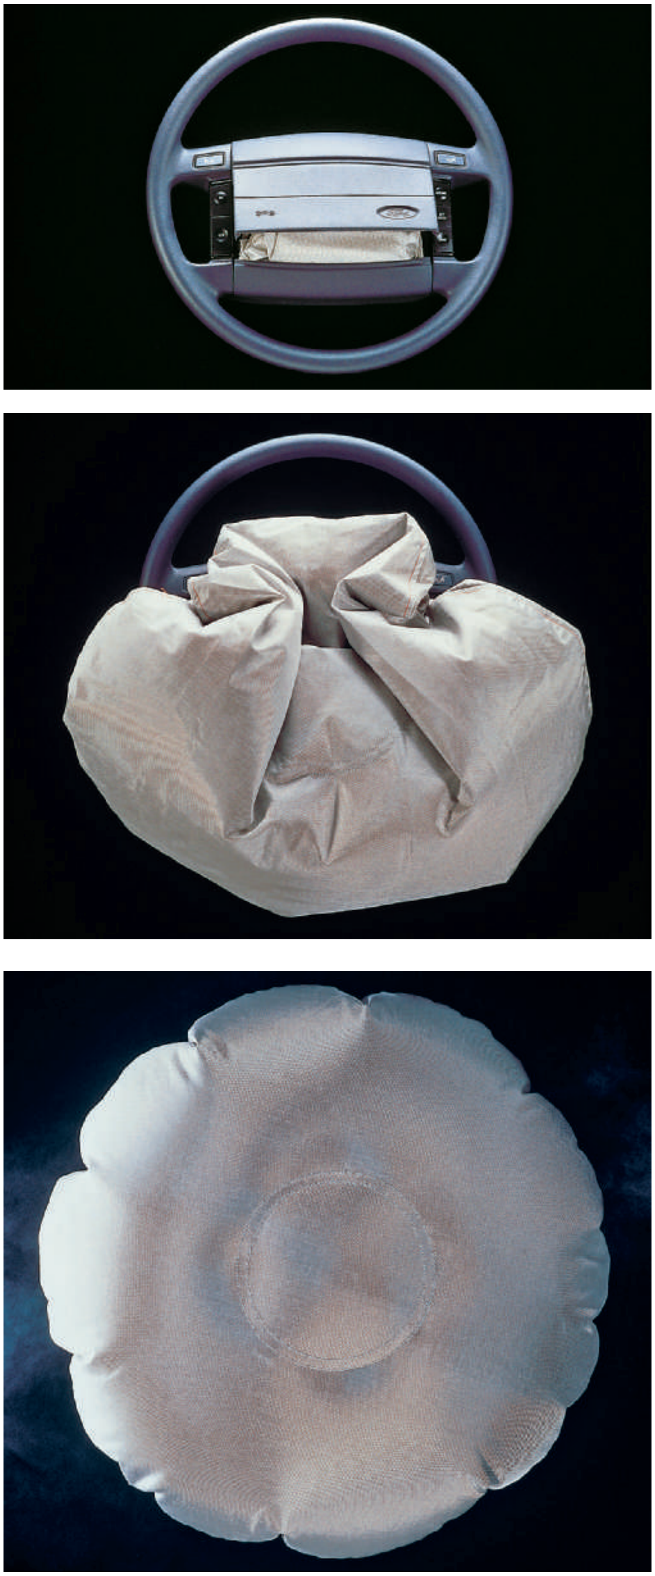
Service Guidelines

Some guidelines for servicing lap and shoulder belts follow:

- Replace the seat belt with a new assembly if there is any abnormality.
- Never disassemble any part of the seat belt system.
- Never attempt repairs on lap or shoulder belt retractors or retractor covers. Replace them if necessary.
- Tighten all anchor bolts to specifications.

Air Bags

An air bag is much like a nylon balloon that quickly inflates to stop the forward movement of the occupant's upper body during a collision. Air bags are designed to be used *with* seat belts, not replace them. If there is a collision, an air bag takes less than 1 second to protect the driver and/or passengers **(Figure 48–9)**. Consider this sequence:



Courtesy of TRW, Incorporated.

FIGURE 48–9 Various stages of air bag inflation.

- Time zero—Impact begins and the air bag system is doing nothing.
- Twenty milliseconds later—The sensors are sending an impact signal to the air bag module and the air bag begins to inflate.

- Three milliseconds later (total time from impact is now 23 milliseconds)—The air bag is inflated and is up against the occupant's chest. The occupant's body has not yet begun to move as a result of the impact.
- Seventeen milliseconds later (total time from impact is now 40 milliseconds)—The air bag is almost fully deployed and the occupant's body begins to move forward because of the impact.
- Thirty milliseconds later (total time from impact is just 70 milliseconds)—The air bag begins to absorb the forward movement of the occupant and the air bag begins to deflate through its vents. Once the air bag deflates, its job is over.

The systems and parts used to deploy an air bag vary with the year and manufacturer of the vehicle, as well as the locations of the air bags. An air bag is inflated or deployed by rapid expansion (explosion) of a gas. The gas is fired by an igniter commonly called a **squib**.

Different manufacturers also call their air bag systems by different names, such as **supplemental inflatable restraint (SIR)** and **supplemental restraint system (SRS)**. All late-model vehicles have a driver-side and a passenger-side air bag **(Figure 48–10)**. Most late-model vehicles have side impact, knee, and curtain air bags as well.

Passenger-side air bag modules are located in the vehicle's dash. These air bags are very similar in design and operation to those on the driver's side. However, many manufacturers use a different set of sensors. The actual capacity of gas required to inflate the passenger-side air bag is much greater because the bag must span the extra distance between the occupant and the dashboard. The steering wheel and column make up this difference on the driver's side.

FIGURE 48–10 A passenger air bag.

A driver-side and passenger-side air bag system may include a knee diverter, also called a knee bolster. This unit is designed to help restrain the lower parts of the bodies of the driver and front passenger and prevent the driver from sliding under the air bag during a collision. It is located underneath the steering column and behind the steering column trim. In 2015, Ford introduced a new passenger knee airbag design. This new airbag has an inflatable, molded plastic bladder that is wedged between the inner and outer glove compartment door panels. When a collision occurs, the bladder inflates to fill the space between the dash and the passenger's lower legs. This action reduces the movement of the passenger's pelvic area and back, thereby reducing the load on the pelvis area.

Some vehicles have front and rear seat cushion air bags that inflate the front of the seat cushion to restrain the occupant's lower hip. This helps dampen the impact energy that acts on the occupant's upper body, including the head and chest.

Because of the concern for babies and small children, pickups and other two-seat vehicles either do not have a passenger-side SIR or have a switch that prevents it from deploying. The switch is typically operated with a key to activate or deactivate the SIR. On some vehicles, the passenger air bag is turned on and off through the driver information center. An indicator light in the instrument panel shows the current status of the passenger-side SIR.

Side Air Bags

On many vehicles the occupants may be further protected by side air bags and/or side curtain air bags **(Figure 48–11)**. The rear passengers may be protected by air bags in the rear of the front seat backs, side air bags, and/or the side curtain air bags.

Side air bags can take on many different shapes and are deployed from various locations. Side curtains

(Figure 48–12) blanket the entire side of the car. Side air bags **(Figure 48–13)** are available for the front and rear doors on some cars. These air bags are deployed from the interior trim on the door or from the outside of the seat. Curtain air bags are located inside the headliner and extend from the driver's and front passenger's front pillars to the rear pillars behind the rear seat. Each air bag is a one-piece unit.

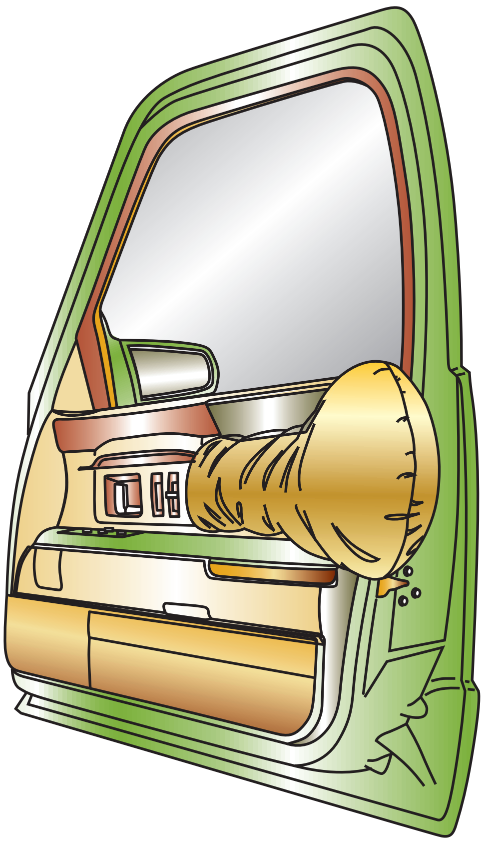

FIGURE 48–13 A side air bag.

Side head protection systems inflate a long, narrow air bag that extends from the windshield area to the back of the front seat **(Figure 48–14)**.

When a side impact air bag is deployed: the front side, rear side, and curtain shield air bags are deployed at the same time. Door-mounted side air bags must begin deploying in 5 to 6 milliseconds. This requirement is based on the fact that only a few inches separate the occupant from the other vehicle during a side impact. Seat-back-mounted side air bags do not need to operate at these great speeds. The head air bag is designed to stay inflated for about 5 seconds to offer protection against a second or third impact.

Current air bag systems work in conjunction with the seat belt pretensioners and retractors. When the air bag circuit is turned on, so is the pretensioner circuit. These actions limit the movement of the occupants.

Inflatable Seat Belts

An inflatable seat belt can control the movement of a passenger's head and neck during a crash. This inflatable belt spreads the crash forces over more of the body than a standard belt. The shoulder strap contains a folded, cylindrical air bag that is deployed during a collision **(Figure 48–15)**. These belts are found in the rear seats of a few SUVs and some cars. They are designed to protect the fragile bones of passengers, especially older adults and children, who are very vulnerable to chest, head, and neck injuries.

Front Center Air Bags

In 2013, General Motors introduced a front center airbag on some models. This tubular airbag deploys

FIGURE 48–15 An inflatable shoulder harness, which controls a person's forward movement when the seat belt tightens during a collision.

from the right side of the driver's seat and fills the void between the front seats near the center of the vehicle. This airbag is designed to offer some restraint during passenger-side crashes when the driver is alone, it also acts as an energy-absorbing cushion between driver and front passenger in both driver- and passenger-side crashes.

Second-Generation Air Bags

Newer vehicles are equipped with second-generation air bags that inflate with less force than earlier air bags. The air bags are depowered by reducing the peak inflation pressure and/or the force and speed at which an air bag inflates. These systems reduce the number of injuries caused by the air bag itself. Depending on the specific model vehicle, air bag size, and seat belt system, a second-generation air bag inflates with an average of 20 percent to 35 percent less energy.

Adaptive SRS Systems

All 2006 and newer vehicles must have a system that allows for air bag suppression when infants, children, or small adults are in the front passenger seat. This system uses a load sensor, seat belt tension sensor, and an electronic control unit **(Figure 48–16)**. The load sensor measures the weight on the seat and classifies the occupant as an adult or child and provides the classification to the air bag controller, which enables or suppresses passenger air bag deployment. A belt tension sensor identifies cinched child seats.

Newer vehicles have "**smart**" or **adaptive air bags**. Many of these systems have two possible stages of air bag deployment. The force of the expanding air bag is controlled to match the severity of the impact and/or by the size and weight of the seat's occupant **(Figure 48–17)**. Other things considered are seat-track position and seat belt use. All of these factors require different deployment rates.

FIGURE 48–16 An occupant detection system with a seat belt tension sensor.

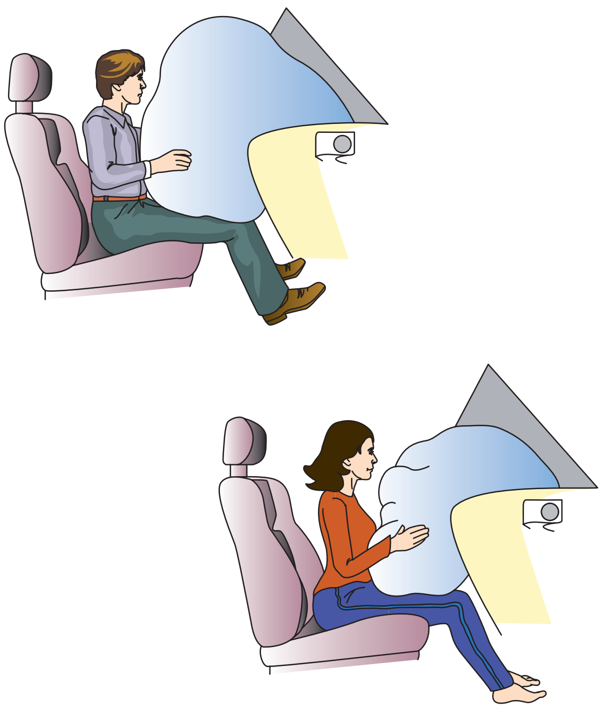

FIGURE 48–17 (Top) Full strength air bag deployment because of the weight of the occupant. (Bottom) Reduced air bag deployment because of the weight of the occupant.

Two-stage air bags have one air bag, two containers of gas, and two squibs. When low-pressure deployment is desired, only one squib is fired. Depending on the system, the second stage may fire just after the first, providing a longer inflation time with less force. A severe collision can fire both igniters simultaneously. The air bag sensor assembly calculates the extent of impact, seat position, and status of the seat belts and controls the inflation times for the two chambers.

Mechanical Air Bag Systems

Mechanical air bag systems are found in some vehicles (early Toyotas, Volvos, and Jaguars). These systems are totally independent systems and do not rely on electricity or electronics to deploy. They have a mechanical trigger that ignites the propellant to deploy the air bag. The trigger is an impact sensor with a firing pin. During an impact, the firing pin moves and ignites a primer that ignites sodium azide pellets inside a gas generator. The gases released by the burning pellets inflate the air bag. This type of system is often used to equip a vehicle with air bags when it was not originally fitted with them.

Mechanical air bag systems can be used at any location in the vehicle. The number of gas generators used in each type of air bag depends on the size of the air bag. For example, a side impact air bag may have two generators and a side curtain can have as many as eight generators.

Electrical System Components

The electrical circuit of an air bag system includes impact sensors and an electronic control module. The electrical system conducts a system self-check to let the driver know that it is functioning properly, records DTCs for technician use, detects an impact, and sends a signal to deploy the air bags.

A vehicle can contain many different air bag modules **(Figure 48–18)**. The driver-side, passenger-side, side, and curtain air bag modules each has an inflator (igniter), air bag, and an ignition unit (cracker, igniter charger, gas). When the sensors send a signal to the module, current flows into the inflator and activates the ignition material to deploy the air bag.

To prevent accidental deployment, most systems require that at least two sensor switches be closed before an air bag is deployed **(Figure 48–19)**. The number of sensors used in a system depends on the design of the system. Normally, sensors are located in the engine and passenger compartments.

Sensors

Typically, ignition of the air bag only occurs when an outside (impact or crash) sensor and an inside (safing or arming) sensor are closed. Once the two sensors are closed, the electrical circuit to the igniter is complete.

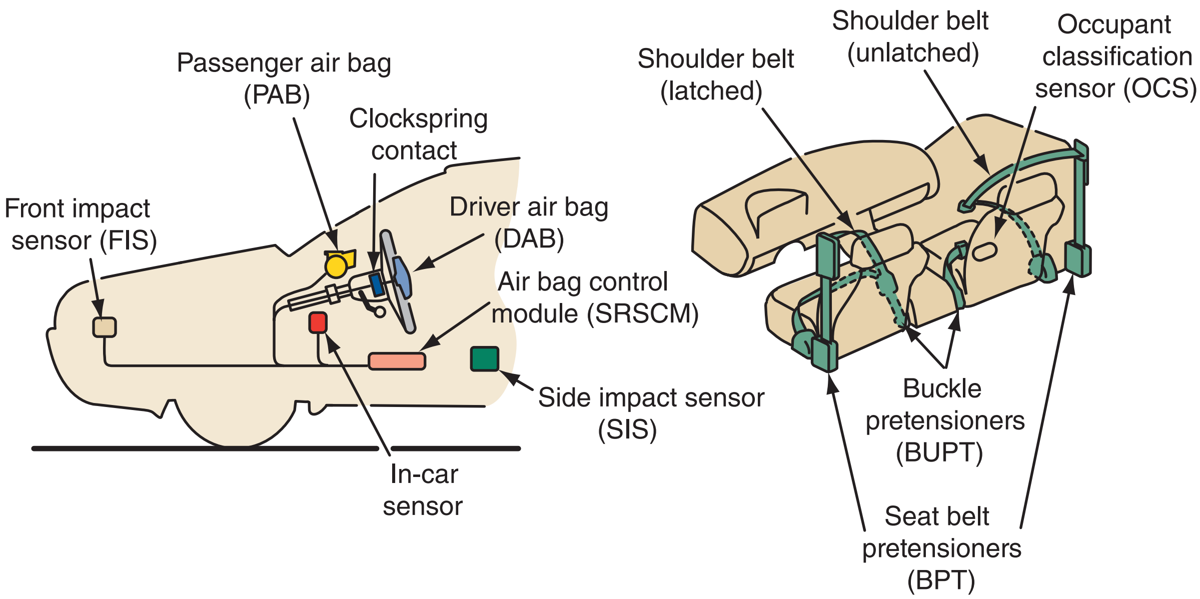

FIGURE 48–18 Location of common SRS components.

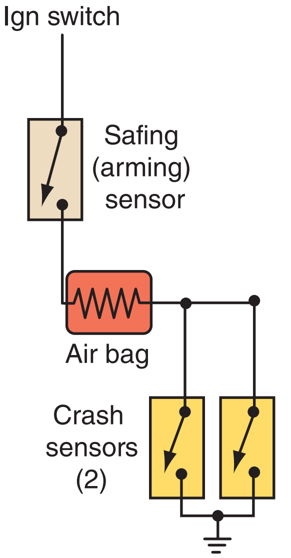

FIGURE 48–19 A simple air bag circuit with sensors.

Impact—Safing Sensors There are three basic types of safing sensors:

Roller-Type. These have a roller located on a ramp **(Figure 48–20)**. One terminal of the sensor is connected to the ramp. The other terminal is connected to a spring contact extending through an opening in the ramp but not touching the ramp. Small springs hold the roller against a stop. During a heavy impact, the roller moves up the ramp and strikes the spring contact. This completes the circuit between the ramp and the spring, and the air bag deploys.

Mass-Type. This sensor has a normally open set of gold-plated switch contacts and ball. The ball is the sensing mass and is held in place by a magnet **(Figure 48–21)**. When there is sufficient force, the ball breaks loose and makes contact with the electrical contacts to complete the circuit. Other similar systems rely on a mass-type sensor that has a pivoted weight connected to a movable contact that completes the circuit when moved.

Accelerometer. This is a piezoelectric element that is distorted during a collision **(Figure 48–22)**. It generates an analog voltage that reflects the strength of the deceleration forces.

Seat Position Sensor The seat position sensor is mounted on the inner rail of the front seats **(Figure 48–23)**. The sensor is basically a magnet and a Hall-effect switch. The sensor is used to detect when the seat is in the forward position. When the seat is in a rearward position, the rail is close to the seat position

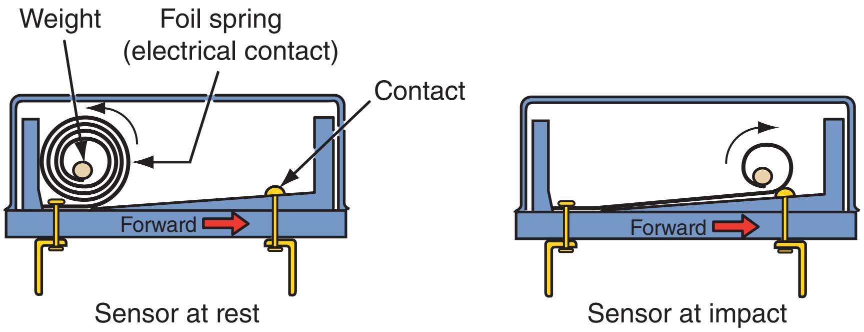

FIGURE 48–20 A roller-type air bag sensor.

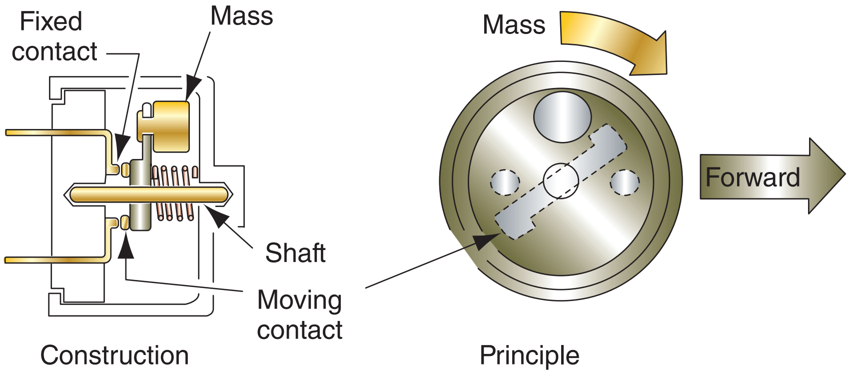

FIGURE 48–21 A mass-type sensor with a pivoted weight connected to a movable contact.

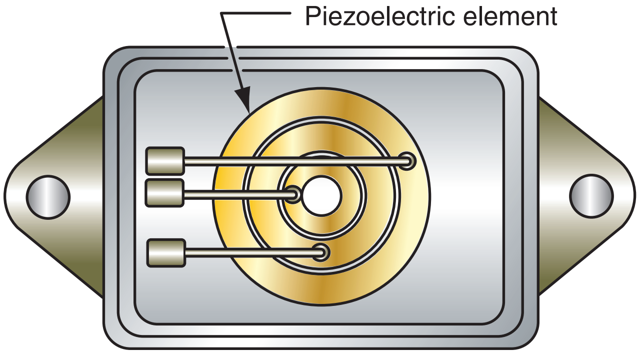

FIGURE 48–22 An accelerometer air bag sensor.

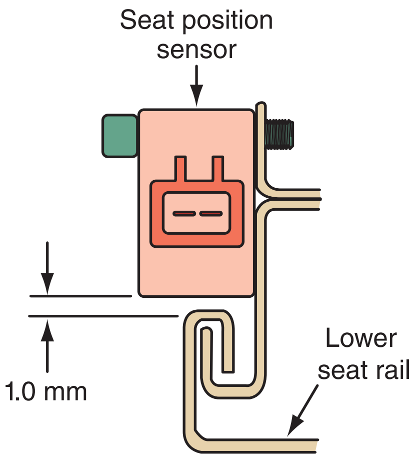

FIGURE 48–23 The seat position sensor has a specified gap between the sensor and the lower seat rail.

sensor. When it is in the forward position, the distance between the rail and the sensor becomes larger. The position of the rail in relation to the Hall-effect switch determines the signal the sensor sends to the air bag sensor assembly. When the seat is close to the steering wheel, the air bag deploys with less pressure.

Seat Belt Buckle Switch The seat belt buckle switch detects whether or not the seat belt is fastened. It also is a Hall-effect switch and magnet. The magnetic field changes as the seat belt is fastened and unfastened. The SRS system adjusts the force of the air bags according to this input.

Occupant Classification Sensor

To determine the force of the front and side passenger air bags, the weight of the occupant is measured. If there is no occupant, the air bags will not deploy during a collision. Most passenger occupant classification sensors use a bladder placed beneath the seat cushion. The bladder is connected to a pressure sensor that sends a signal to the control unit for the air bags. The bladder is a silicone-filled gel mat. When there is weight on the seat cushion, pressure is applied to the silicone in the mat. The pressure sensor measures that pressure and converts it to voltage signals **(Figure 48–24)**.

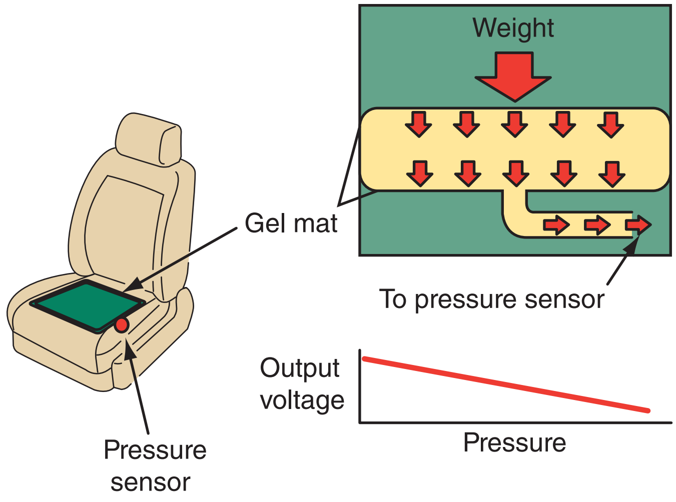

FIGURE 48–24 A gel mat-type occupant classification sensor.

Other occupant classification sensors are made up of two sheets of electrodes separated by a spacer. Weight on the seat causes the electrodes to contact each other through a hole in the spacer. The weight on the seat determines the contact area of the sheets. The amount of conductance between the sheets is used to determine weight.

The occupant classification sensor, seat belt tension sensor, and seat belt buckle switch send signals to the control unit. The control unit then determines if the seat is occupied, and if the seat is occupied by an adult, a child, or a child in a booster seat. The latter is detected by the seat belt tension sensor. When a child seat is sitting on the seat cushion, seat belt tension pulls the child seat down, adding pressure to the seat cushion. This pressure, plus the weight of the child and the child seat, is sensed by the weight detection sensor.

Diagnostic Monitor Assembly The air bag sensing diagnostic monitor (ASDM) constantly monitors the readiness of the SIR electrical system. If the module determines there is a fault, it will illuminate the warning lamp. Depending on the fault, the SIR system may be disarmed until the fault is corrected.

The diagnostic module also supplies back-up power to the air bag module in the event that the battery or cables are damaged during the accident. The stored charge can last up to 30 minutes after the battery has been disconnected.

Warning! The back-up power supply must be depleted before any air bag service is performed. To deplete this back-up power, refer to the service information. This may require removing fuses or disconnecting the battery and waiting for at least 30 minutes.

Wiring Harness

For identification and safety purposes, the electrical harnesses of the SIR system typically have yellow connectors. Each connector has a special function and is designed specifically for the SRS. To increase their reliability, all SRS connectors have durable gold-plated terminals and are placed in specific locations. The connectors also have a shorting bar, called an activation prevention mechanism, that prevents accidental deployment while being serviced.

Single-stage air bags have one inflator and one pair of wires that connect to the air bag module. Two-stage air bags have two inflators and two pairs of wires connected to the air bag module.

Clockspring The **clockspring** allows for electrical contact to the air bag module at all times. Since the air bag module sits in the center of the steering wheel, the clockspring is designed to provide voltage to the module regardless of steering wheel position. The clockspring is located between the steering wheel and the steering column **(Figure 48–25)**.

The clockspring's electrical connector contains a long conductive ribbon. The wires from the air bag's electrical system are connected from the underside of the clockspring to the conductive ribbon. The other end of the ribbon is connected to the air bag module. When the steering wheel is turned, the ribbon coils and uncoils without breaking the electrical connection.

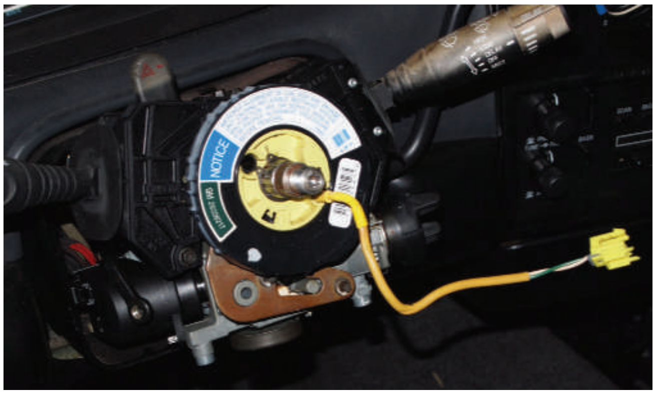

FIGURE 48–25 A clockspring.

SIR or Air Bag Readiness Light This light lets the driver know the air bag system is ready to do its job. The warning lamp is operated by the diagnostic module. The readiness lamp lights briefly when the driver turns the ignition key from off to run. The lamp should go out once the engine is running. A malfunction in the air bag system causes the light to stay on continuously or to flash. Some systems have a tone generator that sounds if there is a problem in the system or if the readiness light is not functioning.

Vehicles with side impact air bags have a light that informs the driver if the side impact bags are turned off **(Figure 48–26)**. This is common when objects, such as boxes or packages are placed on the passenger seat. The occupant detection system determines the weight is not a person and turns off the side impact airbags.

Air Bag Module

The air bag module is the air bag and inflator assembly packaged into a single unit or module. The module is located in the steering wheel for the driver and in the dash panel for the front-seat passenger **(Figure 48–27)**. The various types of side protection

FIGURE 48–26 An example of a side impact air bag indicator light.

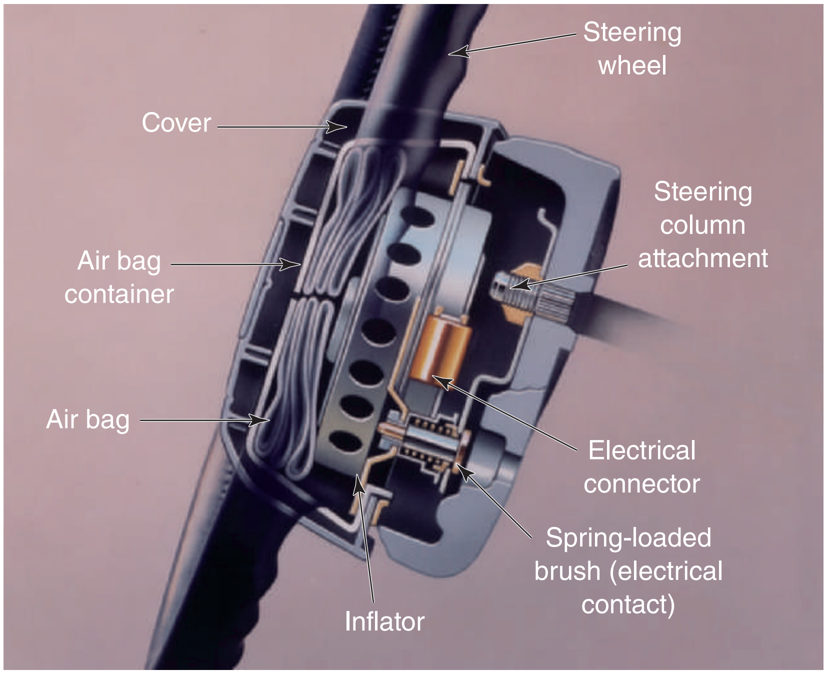

FIGURE 48–27 A cutaway view of an air bag module.

air bags have the module located at the point where the bag is deployed.

The inflation of the air bag is typically accomplished through an explosive release of nitrogen gas. The igniter **(Figure 48–28)** is an integral part of the inflator assembly. It starts a chemical reaction to inflate the air bag. At the center of the igniter assembly is the squib, which contains **zeronic potassium perchlorate (ZPP)**. When voltage is supplied through the squib, an electrical arc is formed between two pins. The spark ignites the gas generator and causes a rapid expansion of the gas, which deploys, or inflates, the air bag.

The inflation assembly is composed of a gas generator (called a generant) containing sodium azide and copper oxide or potassium nitrate propellant. The ZPP ignites the propellant charge. During ignition, large quantities of hot, expanding nitrogen gas are produced very quickly and quickly inflate the air bag. As the nitrogen moves into the air bag, it is filtered to remove sodium hydroxide dust formed during the chemical reaction.

Caution! **Wear gloves and eye protection when handling a deployed air bag module. Sodium hydroxide residue may remain on the bag and cause a skin irritation.**

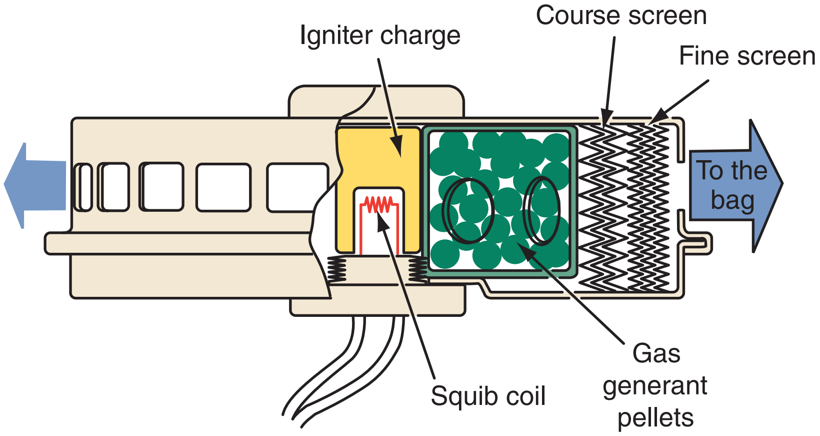

FIGURE 48–28 The action of an air bag module releasing nitrogen gas to an air bag.

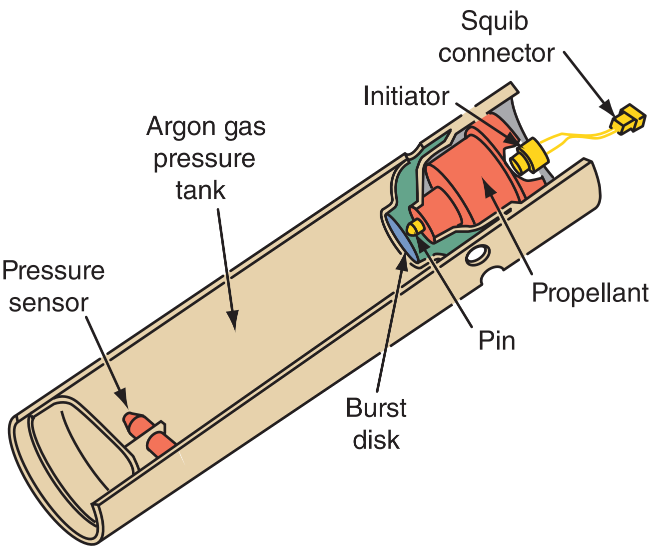

FIGURE 48–29 An inflator module that uses argon gas.

Not all air bags use nitrogen gas to inflate the bag; some use a solid propellant and compressed argon gas **(Figure 48–29)**. Argon has a stable structure, cools more quickly, and is inert as well as nontoxic. Argon is commonly used for passenger-side and side protection air bags.

A mounting plate and retainer ring attach the air bag assembly to the inflator. They also keep the entire air bag module connected to the steering wheel.

The bag itself is made of a thin, nylon fabric that is folded into the steering wheel, dash, seat, or door. The powdery substance released from the air bag when it is deployed is regular cornstarch or talcum powder. These powders are used by the air bag manufacturers to keep air bags lubricated and pliable while they are in storage. The entire module must be replaced as one unit when repair of the air bag system is required.

Diagnosis

Before diagnosing the system, perform a system check by observing the air bag warning light and comparing your findings with those described in the service information for the vehicle. To check the status of the air bag system, make sure the ignition has been off for at least 2 seconds. Then turn the ignition on. The SRS warning lamp should turn on and remain on for about 6 seconds. During this time, the system is performing a preliminary check of the system, including the pretensioners.

If the system detects a problem, the SRS warning light will remain on. If the lamp flashes or turns off and then turns on again, low source voltage may be indicated. A system problem is also indicated when the lamp does not come on when the ignition is initially turned on.

If any of these conditions are present, the system needs to be checked. Begin diagnosis by connecting a scan tool and attempting to communicate with the air bag system. On some older systems, the air bag light displays flash codes by blinking the fault light once a diagnostic connected is shorted. Testing should also include a thorough visual inspection of system components when diagnosing a system that is disarmed because of a fault. Damage from a collision or mishandling during a nonrelated repair can set up a fault area, which will disarm the air bag system.

The passenger air bag indicator should also be observed. Its display is an indication of the condition of the passenger weight sensor as well as the air bag's modules. Always refer to the service information to interpret the indicators. Normal displays will vary with what is detected in the passenger seat. If a problem is detected, the SRS warning lamp will be lit, as will the passenger air bag "OFF" indicator.

If the action of the warning lamp indicates a problem, the system should be checked for DTCs. If there is a problem in the passenger side, check the DTCs in the air bag system first. Then check the occupant classification system.

Retrieving Trouble Codes

If the system detects a problem in the SRS system, the malfunction data will be stored in memory and the warning indicator will be lit. Normally two types of faults are stored. Active DTCs will turn the air bag warning lamp on, whereas stored codes are intermittent problems and probably will not turn on the warning lamp.

SRS problems are difficult to verify; therefore, DTCs are extremely important for troubleshooting the system. Most systems have two- and five-digit DTCs. The two-digit codes are flash codes displayed with the SRS warning indicator. The five-digit codes are displayed on a scan tool. It is important to note that when the negative battery cable is disconnected, the system's memory is erased. Therefore, DTCs should be retrieved before disconnecting the battery.

Flash Codes On vehicles that display codes with the warning light or on the digital instrument panel, make sure you follow the procedure prescribed by the manufacturer to retrieve the codes. Normally a jumper wire is connected across two terminals in the DLC with the ignition switch on. Make sure the wire

is connected correctly and does not contact other pins in the connector. Once the jumper is in place, observe the action of the SRS warning lamp. Count the blinks and refer to the manufacturer's code table to interpret the code. If there is more than one stored DTC, the second code will flash shortly after the first code is displayed. In most cases, the codes will be erased when the ignition is turned off.

Scan Tool DTC Retrieval To retrieve codes, connect the scan tool **(Figure 48–30)** to the DLC and turn the ignition on. Follow the instructions for the scan tool to retrieve air bag information. Record all stored and active codes. Diagnose the cause of the codes in order, from the lowest number to the highest. Stored codes can be erased with the scan tool but active codes will only be erased when the problem is corrected.

Once the codes are retrieved, refer to the manufacturer's information to identify the steps for isolating and correcting the problem.

> **Caution!** Testing individual parts of the system must be done with care. Not following the correct procedure or using the wrong tools can cause an air bag to deploy. This is not only dangerous but it is also very expensive. Never attempt to check the resistance of an air bag module.

FIGURE 48-31 An air bag simulator is used as a substitute for the actual air bag during testing.

Air Bag Simulator To safely test SRS components, the use of an air bag simulator **(Figure 48–31)** is recommended. This simulator is installed in place of the air bag. The simulator can be adjusted to provide the normal electrical load of the air bag, thereby allowing accurate testing of the circuits without the fear of accidental air bag deployment.

Servicing the Air Bag System

Whenever working on or around air bag systems, it is important to follow all safety warnings **(Figure 48–32)**. Examples of these warnings follow:

1. When performing any work on the inside of a vehicle, make sure you are aware of the location of all air bags and exercise caution when working in those areas.
2. Wear safety glasses when servicing the air bag system.
3. Wait at least 5 minutes after disabling the system before beginning any service on or around the air bag system. The reserve energy module stores enough power to deploy the air bag after battery voltage is lost.

FIGURE 48-32 One example of an air bag warning label.

4. Always follow service procedures exactly as given by the manufacturer. Failure to do this can cause the SRS to deploy. Also, if the system is not serviced properly, it may not work when it needs to.
5. Never disassemble or attempt to repair any parts in order to reuse them; always replace them with new ones.
6. Handle all air bag sensors with care. Do not strike or jar a sensor in such a manner that deployment may occur.
7. When carrying a live air bag module, face the trim and bag away from your body.
8. Do not carry the module by its wires or connector.
9. When placing a live module on a bench, face the trim and air bag up.
10. Deployed air bags may have a powdery residue on them. Sodium hydroxide is produced by the deployment reaction and is converted to sodium carbonate when it comes into contact with atmospheric moisture. It is unlikely that sodium hydroxide will still be present. However, wear safety glasses and gloves when handling a deployed air bag. Wash your hands immediately after handling the bag.
11. A live air bag module must be deployed before disposal. Because the deployment of an air bag is through an explosive process, improper disposal may result in injury and fines. A deployed air bag should be disposed of according to EPA and manufacturer procedures.
12. Do not use a battery- or AC-powered voltmeter, ohmmeter, or any other type of test equipment not specified in the service information to test the air bag module. Never use a testlight to probe for voltage.
13. After work on the SRS is completed, perform the SRS warning light check.

Disarming Mechanical Systems

Because mechanical air bag systems are not tied to the electrical system, they cannot be deactivated by disconnecting the battery. The parts responsible for triggering the air bags and seat belt pretensioners are marked with “Danger Zone” in red. In some cases, the air bags cannot be deactivated and care must be taken not to jar the vehicle or close a door with an obstacle between the door and seat. To disarm other systems, certain cables need to be disconnected or cut. For example, on Volvos with side air bags, it is a black ribbed cable located between the bottom and back cushions of the seat. Always check the service information before working on or near these systems.

Service Guidelines

An air bag module is serviced as a complete assembly. Technicians repairing these systems are also advised to service crash sensors, mercury switches, and any other related components in assembly

Caution! A two-stage air bag may appear to be fully deployed when only its first stage has deployed. Care must be taken to make sure that two-stage air bag has been fully deployed before handling them. Always assume that any deployed two-stage air bag has an active stage two. Improper handling or servicing can activate the inflator module and cause personal injury. Always follow the manufacturer’s recommended handling procedures.

groupings. A damaged crash sensor must be replaced. It is a good idea to replace the entire set if a failure or degradation of any single sensor is found. Typically, when an air bag or bags have deployed, the control module and sensors must be replaced in addition to the air bags. This is because permanent codes or latch codes are stored in the air bag control module. These codes cannot be erased and only a new module will reactivate the system. The new control module will likely need to be programmed with a scan tool once installed.

Photo Sequence 46 covers a typical procedure for replacing an air bag module.

The steering column clockspring should be maintained in its correct index position at all times. Failure to do so can cause damage to the enclosure, wiring, or module. Any of these situations can cause the air bag system to default into a nonoperative mode. The clockspring should be replaced any time it has been removed.

Before returning the vehicle to the customer after service, make sure the sensors are firmly fastened to their mounting fixtures, with their arrows facing forward. Be certain all the fuses are correctly rated and replaced. Make sure a final check is made for codes using the approved scan tool. Carefully recheck the wire and harness routing before releasing the car.

Other Protection Systems

To make vehicles safe and to protect the occupants inside the vehicle, manufacturers include many different systems and options. What follows is a quick look at a few of these. By no means is this discussion conclusive; there are many things about how a vehicle is made that influence the protection and safety it offers. Basically, cars that offer good protection are those that are constructed to maintain integrity when impacted on. This construction includes side door beams, crumple zones, and reinforced areas of the frame.

Crumple zones are areas of the body that will bend or break away to protect the passengers inside the vehicle. These crumple zones absorb or take on the impact while keeping the passenger compartment undisturbed.

Headrests

Nearly two-thirds of all injuries from collisions are soft-tissue related, commonly referred to as whiplash. Good head restraints and proper adjustment help prevent these injuries. A properly adjusted headrest stops the head and neck from extending backward on impact. Nine out of ten people do not adjust the headrest for their height and comfort. A headrest should be positioned at least to the top of their ear and less than 4 inches (10 cm) from the back of their head.

New systems that automatically adjust the headrest have been developed. These headrest systems move the headrest up and forward when the vehicle is hit from behind. If the vehicle was in a collision, the action of the headrest should be checked. This is done by measuring the amount the headrest can be moved **(Figure 48–33)**.

Event Data Recorder (EDR)

Newer air bag systems have an event data recorder (EDR) that records data from a crash or a near crash. The recorder is normally inside the air bag control module assembly. It records air bag system diagnostic data, air bag deployment data, seat belt status, engine speed, throttle and brake pedal data, position of the transmission selector, and position of the driver's seat.

Precollision System

A precollision system predicts possible collisions with an obstacle, based on information it receives from various sensors. The system uses a millimeter wave radar sensor to predict a possible collision and retracts the seat belts before the collision. The inputs also are used to control the brake system. Millimeter wave radar uses an extremely high frequency with an extremely short wavelength. Millimeter wave radar does a good job at recognizing obstacles.

The precollision system removes the slack in the front seat belts and warns the driver of an impending collision. The sensor only detects metal objects and

will not respond to people, bicycles, trees, and animals. It also will not respond if the seat belts are not buckled.

Rollover Protection

Some convertibles have a built-in roll bar to protect the passengers in case of a rollover. These units are permanent structures of the vehicle. Others have automatic systems that provide for this. They deploy a roll bar from behind the headrests when the vehicle experiences extreme tilting, when the wheels lose contact with the ground, or during a serious accident **(Figure 48–34)**.

Vehicles with rollover protection use sensors to monitor the speed of the rollover and inflate the air bags accordingly. During a rollover, the air bags stay inflated for a longer than normal time to keep the occupants safe until the vehicle comes to a rest. These systems also take the slack out of the seat belts, shut off the fuel pump, and disconnect the battery when a rollover is sensed.

Hybrid vehicles also have a rollover protection feature. This system isolates the high-voltage circuits whenever the air bags are deployed.

Four-Point Seat Belts

Although not in use at this time, Ford Motor Company and other companies are studying the use of four-point seat belts. This belt system has two shoulder straps integrated into the frame of the seat. The shoulder straps and the two lap belts buckle together at the center of the passenger's waist. The design allows the forces from a crash to be evenly distributed across the body.

Wheel Alignment

A vehicle's wheels, tires, suspension system, and steering system are all designed to work together to provide safe, stable, and reliable handling. The goal of these systems working together is proper wheel alignment **(Figure 49–1)**. During an alignment, the angles of the suspension and wheels are measured and adjusted. The procedure places the tires to maximize performance, ride quality, and tire life. These angles are adjusted by changing the position of various steering and suspension parts. The desired angles are those set by the vehicle's manufacturer.

Correct wheel alignment allows the wheels to roll without scuffing, dragging, or slipping on different types of road surfaces. Proper alignment of both the front and rear wheels ensures greater safety, easier steering, longer tire life, reduction in fuel consumption, and less strain on the steering and suspension systems.

The alignment of the wheels should be checked whenever new tires or steering and suspension parts are installed. Also, the wheels should be aligned whenever the tires are wearing abnormally. A vehicle's wheels become out-of-alignment due to worn

suspension parts, a change in ride height, or driving hard into a pothole or curb. All of these can affect the angle of the wheels.

A wheel alignment restores the geometry of the suspension to the angles that were determined to properly locate the vehicle's weight on the tires and to facilitate steering.

Types of Wheel Alignment

For many years and until the 1980s, two-wheel alignments were performed. This is because most vehicles were RWD and had live rear axles that did not allow for four-wheel alignment. Today, since suspension and steering systems are more complex, four-wheel alignments are performed. This is true even if only the alignment of the front-wheels can be adjusted.

Four-wheel alignment measures the angles at the four wheels. On some vehicles, adjustments are made only to the front wheels. This is primarily due to the fact that there is no way to make adjustments to the rear wheels. However, by adjusting the front wheels so they are rotating in the same direction as the rear wheels, the vehicle will tend to move straight. Many vehicles have provisions for adjusting the rear wheels. When this is the case, the rear wheels are adjusted first and then the fronts are aligned to the vehicle's centerline.

Road Crown

Most roads are not designed to be flat. They are paved to slope at a slight angle. This allows water to flow off the road's surface rather than allowing it to accumulate. The angle is called **road crown** and can cause a vehicle to tend to pull toward the right of the road. To compensate for this, different angles may be set at each side of the vehicle.

Alignment Geometry

The proper alignment of a suspension/steering system centers on the accuracy of the following angles.

Caster

Caster is the angle of the steering axis of a wheel from the vertical, as viewed from the side of the vehicle. The forward or rearward tilt from the vertical line **(Figure 49–2)** is caster. Caster is most often the first angle adjusted during an alignment. Tilting the axis forward is negative caster. Tilting backward is positive caster. An example of positive caster is on bicycles and motorcycles. The steering and front forks create positive caster that is easily seen **(Figure 49–3A)**. Sometimes, caster can easily be seen in the suspension system, such as on the Ford Explorer **(Figure 49–3B)**.

Caster is designed to provide steering stability. The caster angle for each wheel on an axle should be equal or very close to equal. Caster can be used to compensate for road crown by setting the right wheel caster slightly more positive than the left. Excessively unequal caster angles cause the vehicle to pull toward the side with less caster. Too much negative caster can cause the vehicle to have sensitive steering at high speeds. The vehicle might wander as a result of negative caster. Caster is not considered to be a tire wearing angle. However, high amounts of caster, as built into some sports cars, affects camber angles as the wheels are turned. A vehicle with high caster settings may experience increased shoulder wear on the tires, especially if driven primarily in the city.

Caster is affected by worn or loose ball joints, strut rods, and control arm bushings. Caster adjustments

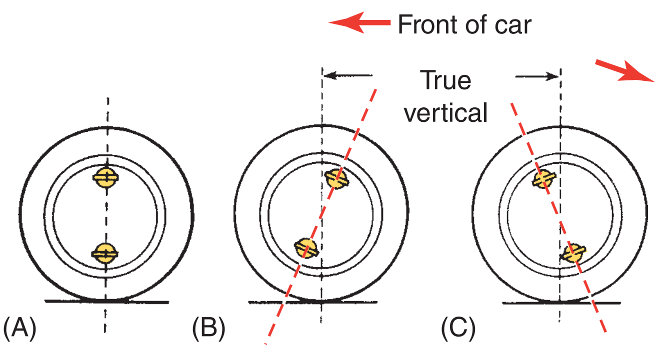

FIGURE 49-2 Three types of caster: (A) zero, (B) positive, and (C) negative.

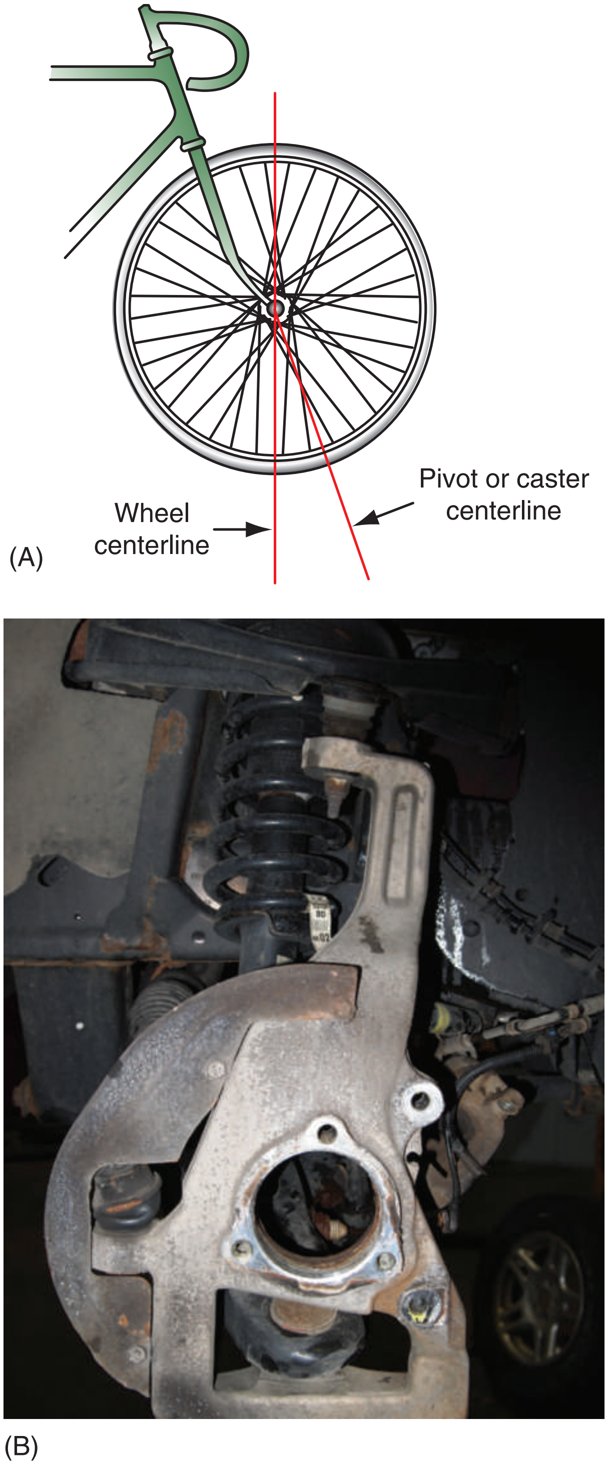

FIGURE 49–3 Caster illustrated as used on a bicycle (A) and as seen built into the front suspension (B).

are not possible on some strut suspension systems without an aftermarket service kit. Often if these vehicles have a caster problem, something is worn or bent and those parts must be replaced or repaired. Where adjustment points are provided, they can be made at the top or bottom mount of the strut assembly.

Camber

Camber is the angle represented by the tilt of either the front or rear wheels inward or outward from the vertical as viewed from the front of the car **(Figure 49–4)**. Camber is designed into the vehicle to compensate for road crown, passenger weight, and vehicle weight. Camber is usually set equally for each wheel. Equal camber means each wheel is tilted outward or inward the same amount. Unequal camber causes the vehicle to pull toward the side that is more positive. Excessive camber causes tire wear.

Camber angle changes, due to the travel of the suspension system, are controlled by the suspension's pivots. Camber is affected by weak or broken springs and worn or loose ball joints, control arm bushings, and wheel bearings. Anything that changes riding height also affects camber.

Camber is adjustable at the control arms on most vehicles. Some vehicles with a strut suspension include a camber adjustment at the spindle assembly. Camber adjustments are also provided on some strut suspension systems at the top mounting of the strut. Very little adjustment of camber (or caster) is required on strut suspensions if the tower and lower control arm locations are correct. If serious camber error has occurred and the suspension mounting positions have not been damaged, it is an indication of bent suspension parts. Damaged parts should be replaced.

Toe

Toe is the distance comparison between the leading edge and trailing edge of the front tires. If the leading edge distance is less, then there is positive toe or toe-in. If it is greater, there is negative toe or toe-out **(Figure 49–5)**. Actually, toe is critical as a tire-wearing angle. Wheels that do not track straight ahead have to drag as they travel forward. Excessive toe measurements (in or out) cause a sawtooth

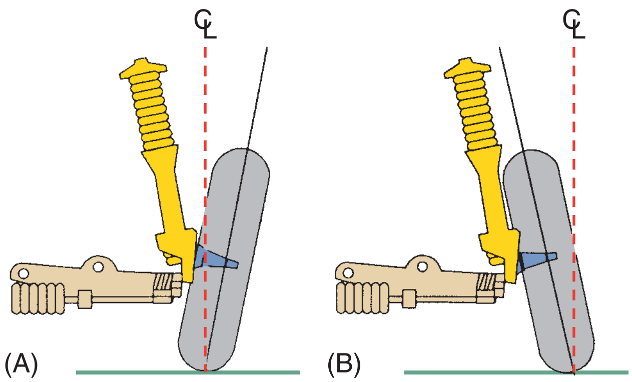

FIGURE 49–4 (A) Positive and (B) negative camber.

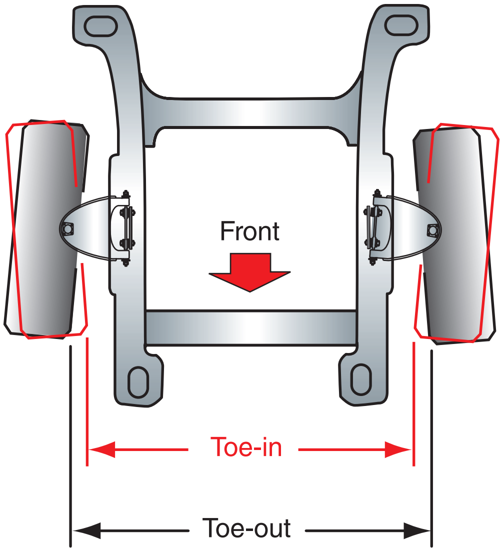

FIGURE 49–5 (Red) Toe-in. (Black) Toe-out.

edge on the tread surface from dragging the tire sideways. Excessive toe-in will cause tire wear on the outside edge of the tire. Toe-out causes wear on the inside edge.

Toe adjustments are made at the tie-rod. They must be set equally on both sides of the car. If the toe settings are not equal, the car may tend to pull due to the steering wheel being off-center. An off-center steering wheel and steering pull should be corrected by making the toe adjustments equal on both sides of the car with the steering wheel centered.

Toe is affected by worn steering linkage components, worn springs, ball joints, or anything that changes camber. Toe changes caused by loose or worn parts often causes bump steer. Bump steer occurs when the vehicle darts left or right after hitting a bump in the road. The change in suspension and/or steering geometry changes the toe, causing the wheels to move left or right.

Toe will change with vehicle speed. As the vehicle moves, friction forces the tires to move straight ahead or have zero toe. However, aerodynamic forces on the vehicle cause a change in its riding height. This will also change the toe as well as camber. Therefore, most toe specifications anticipate these changes and are set to provide zero toe at highway speeds.

Thrust Line

All vehicles are built around a geometric centerline that runs through the center of the chassis from the back to the front. The **thrust line** is the direction the rear axle would travel if unaffected by the front wheels. This condition is also called **tracking**. Correct tracking results from having all suspension parts in their correct location, in good condition, and aligned so that the rear wheels follow directly behind the front wheels while moving in a straight line **(Figure 49–6)**. For this to occur, the axles and wheels must be parallel with one another and the centerlines through the axles and spindles must be at 90-degree angles to the vehicle's centerline. Simply stated, all four wheels should form a perfect rectangle.

A main consideration in any alignment is to make sure the vehicle runs straight down the road, with the rear tires tracking directly behind the front tires when the steering wheel is in the straight-ahead position. The geometric centerline of the vehicle should parallel the road direction. This is the case when rear toe is parallel to the vehicle's geometric centerline in the straight-ahead position. If rear toe does not parallel the vehicle centerline, a thrust direction to the left or right is created **(Figure 49–7)**. This difference of rear toe from the geometric centerline is called the **thrust angle**.

Any time the centerline of the front axle is not parallel to the rear axle, handling will be affected.

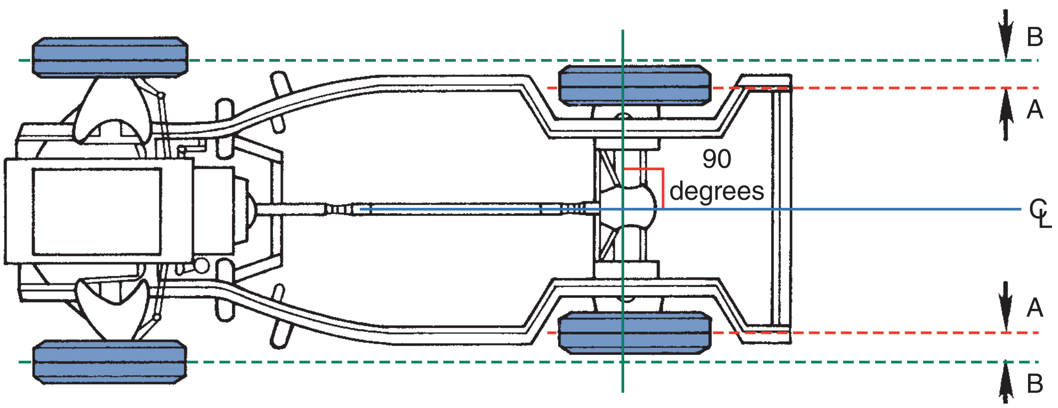

FIGURE 49–6 When a car is tracking correctly, its rear wheels are the same distance from the front wheels on both sides.

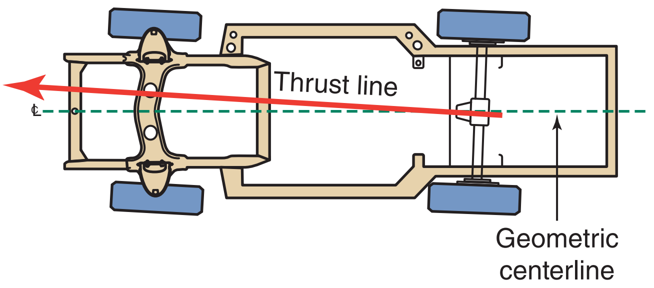

FIGURE 49-7 The thrust line or driving direction of the rear wheels.

This is because the vehicle will tend to travel according to the angle of the rear axle. This causes the vehicle to pull in the opposite direction as the thrust angle. If the thrust line is to the right, the vehicle will pull to the left; when the thrust line is to the left, the vehicle will pull to the right. This can also cause tire wear similar to that of incorrect toe settings. As a general rule, minor variations between the thrust line and centerline are not noticeable and do not cause handling problems as long as the front wheels are aligned parallel with the thrust line.

This problem can cause tire wear and poor directional stability on ice, snow, or wet pavement. It can also make a vehicle pull during braking or hard acceleration. Also, if the thrust angle is not zero, the steering wheel will not be centered. Nonparallel axles, or thrust line deviations, are usually caused by the shifting of the rear axle on its spring supports, rear wheel misalignment, or damage from an accident.

Steering Axis Inclination (SAI)

Steering axis inclination (SAI) locates the vehicle weight to the inside or outside of the vertical centerline of the tire. The SAI is the angle between true vertical and a line drawn between the steering pivots as viewed from the front of the vehicle. It is an engineering angle designed to project the weight of the vehicle to the road surface for stability. The SAI helps the vehicle's steering system return to straight ahead after a turn.

On a short-long arm suspension, SAI is the angle between a true vertical line and a line drawn from the upper ball joint through the lower ball joint. In a strut-equipped vehicle this line is drawn through the center of the strut's upper mount down through the center of the lower ball joint **(Figure 49–8)**.

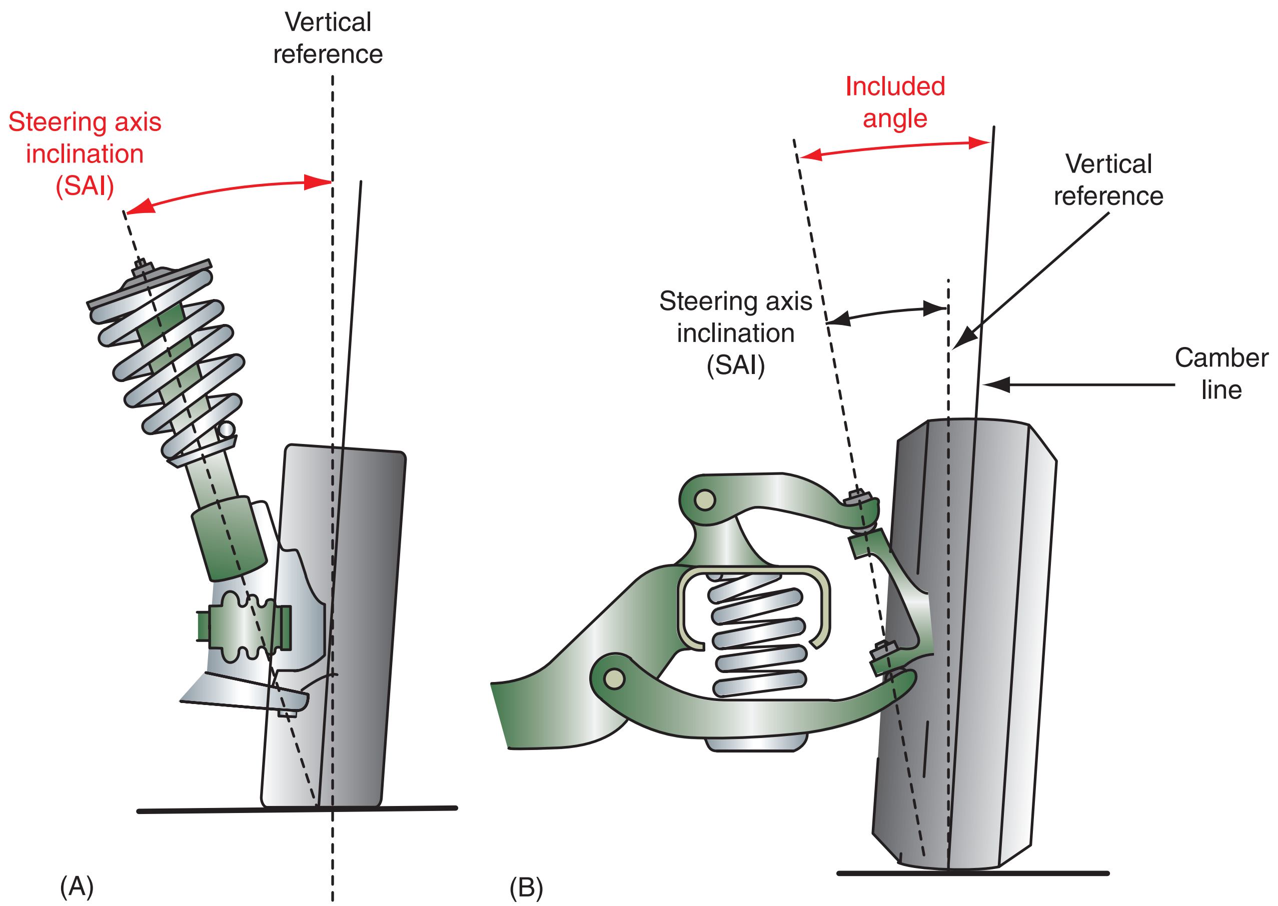

FIGURE 49-8 (A) SAI and (B) included angle (IA) are used to diagnose geometry problems.

If the vehicle has 0 (zero) SAI, the upper and lower ball joints (or strut pivot points) would be located directly over one another. Problems associated with this simple relationship include tire scrub in turns, lack of control, and increased effort during turn recovery. If the SAI is tilted, a triangle is formed between ball joints and spindle. An arc is then formed when turning. There is a high point at straight-ahead position and a drop downward turning to each side. This motion travels through the control arms to the springs and, finally, to the weight of the vehicle. The forces generated in a turn are actually trying to lift the vehicle. The tilting and loading effect of SAI offsets the lifting forces and helps to pull the tires back to straight ahead when the turn is finished.

Front-wheel drive vehicles with strut suspensions typically have a higher SAI angle (12 to 18 degrees) than a short-long arm rear-wheel drive suspension (6 to 8 degrees). This is because the extra leverage provided by a larger angle helps directional stability.

If the SAI angles are unequal side-to-side, torque steer, brake pull, and bump steer (jerking from side to side) can occur even if static camber angles are within specifications.

Checking the SAI angle can help locate various problems that affect wheel alignment. For example, an SAI angle that varies from side to side may indicate an out-of-position upper strut tower, a bowed lower control arm, a bent strut, a bent steering knuckle or spindle, or a shifted center crossmember or cradle.

Scrub Radius

Scrub radius is the distance between the center of the tire and where the SAI angle intersects the ground **(Figure 49–9)**. The scrub radius must be equal on both sides of the vehicle otherwise the vehicle will pull to one side. Scrub radius is not adjustable or measured; rather, it is observed. Scrub radius is part of the suspension's design. There is positive scrub when the tire's contact patch is outside the SAI angle and negative when the patch is inside the angle. Most FWD vehicles have a negative scrub radius. This is done to reduce torque steer. To the contrary, most SLA suspensions have a positive scrub radius. If a vehicle pulls after it has been properly aligned, look for offset wheels or a problem that would affect SAI.

Included Angle

When the camber angle is added to the SAI angle, the sum of the two is called the **included angle (Figure 49–10)**. This angle is not measured by an alignment machine; it is simply obtained by adding the camber and SAI on one side of the vehicle together. The included angle must be the same on each side of the vehicle even if the camber on each side is different. If it is not, the vehicle will pull.

Comparing the SAI, included, and camber angles can help identify damaged or worn components. For example, if the SAI reading is correct but the camber and included angles are less than

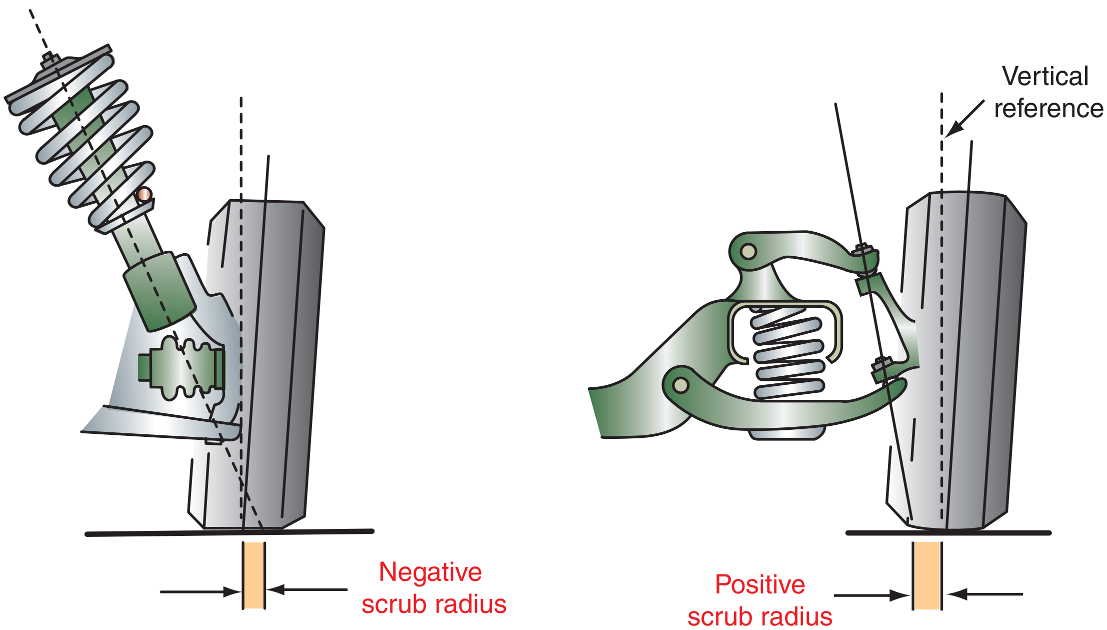

FIGURE 49–9 Scrub radius is affected by wheel size and offset.

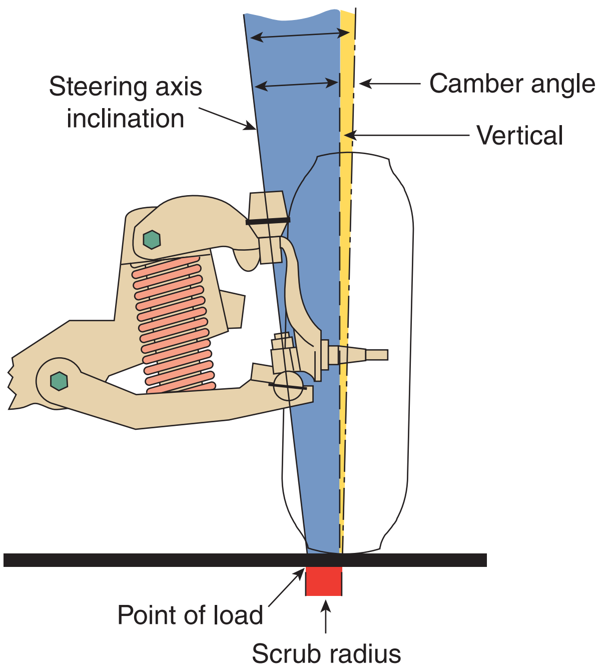

FIGURE 49–10 The included angle is the sum of the camber and SAI angles.

specifications, the steering knuckle or strut tower may be bent. **Table 49–1** summarizes the various angle combinations used to troubleshoot short-long arm, strut, and twin I-beam suspension system alignment problems.

Turning Radius

Turning radius relates to the amount of toe-out present in turns **(Figure 49–11)**. This is also called "toe-out on turns" or "turning angle." As a car goes

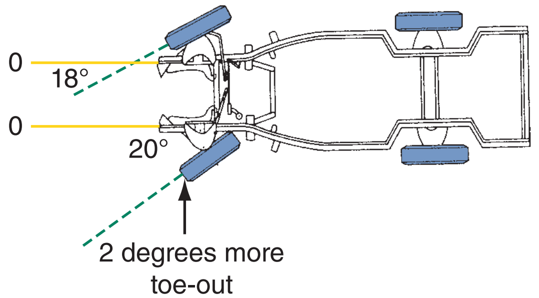

FIGURE 49–11 Turning angle is affected by toe-out on turns.

around a corner, the inside tire must travel in a smaller radius circle than the outside tire. This is accomplished by designing the steering geometry to turn the inside wheel sharper than the outside wheel. The result can be seen as toe-out in turns. This eliminates tire scrubbing on the road surface by keeping the tires pointed in the direction they have to move.

Turning radius is not an adjustable angle. If the angle is not correct, the tie-rods, steering arm, or steering knuckle are damaged and will need to be replaced.

Load Distribution

Load distribution refers to the load placed on each wheel. Every vehicle is engineered to operate at a designed curb height (also called trim height). At this height, each wheel must carry the correct amount of weight. Excessive loading to the front, rear, or one side of the vehicle changes the curb height, upsetting vehicle balance and steering geometry.

In correct alignment, sagging springs and bent suspension parts can also change this condition, upsetting the geometry and placing excessive load on only one or two wheels.

All of these elements—springs, shocks, suspension, and geometry—are engineered to work together as a balanced team to provide safe and comfortable riding and handling. Quite naturally, if one wheel is running under a different condition of weight load and steering geometry, the vehicle does not ride and handle as it is capable of doing.

Prealignment Inspection

Before beginning to align a vehicle, make sure you know why the vehicle needs to be aligned or why the customer has requested an alignment. Often the symptoms will lead to identifying the reason the wheels need to be aligned. Follow the customer interview with a test drive. While driving the car, check to see that the steering wheel is straight. Feel for vibrations in the steering wheel as well as in the floor or seats. Notice any pulling or abnormal handling problems, such as hard steering, tire squeal while cornering, or mechanical pops or clunks. This helps find problems that must be corrected before proceeding with the alignment.

An extremely important part of a wheel alignment is the prealignment inspection. During this inspection, if any parts are found to be defective, they should be replaced before proceeding with the alignment. The inspection should include a careful look at the tires, wheel, suspension system, and steering system. The procedures for inspecting these are detailed in the previous three chapters. A typical alignment inspection report is shown in **Figure 49–12**.

It is important that all abnormal loads be removed before taking any measurements. Obviously, added weight will affect the vehicle's ride height and, therefore, the alignment angles. If the vehicle is normally used to carry heavy objects, such toolboxes, leave them in the vehicle. In some cases, the vehicle manufacturer will specify that a certain amount of weight be added to the vehicle during an alignment. This is done to better reflect the actual driving conditions the vehicle will experience.

Ride Height

Check the vehicle's ride height. Every vehicle is designed to ride at a specific curb height. Curb height specifications and the specific measuring points are given in the service information. Proper alignment is impossible if the ride height is incorrect. This is especially true for camber because as the height of a vehicle changes, so does the camber of the wheels.

GO TO Chapter 46 for a discussion of and the procedure for checking ride height.

Some alignment machines have adapters that allow the unit to measure ride height. This is done without a tape measure; the machine's sensors are installed on the fenders and the measurements are instantly transmitted to the alignment machine **(Figure 49–13)**.

Results of Poor Alignment

If no problems were found during the inspection, a good alignment may take care of the customer's concerns. Poor wheel alignment will cause many different things. Use the chart in **Table 49–2** when checking your work after the alignment.

Wheel Alignment Equipment

There are many different ways to measure the alignment angles on a vehicle. The most common way is the use of an alignment machine or rack. The equipment used for checking alignment angles has evolved from string and measuring tapes to computerized machines. Today, computerized machines are the most commonly used **(Figure 49–14)**. A typical computerized system gives information on a screen to guide the technician step-by-step through the alignment process.

Alignment Machine Care

The alignment machine is a precise piece of equipment; therefore, it needs to be taken care of. Failure to do so will lead to incorrect measurements and adjustments. Alignment racks and machines should be periodically checked and calibrated. This can be done by a technician from the manufacturer, or the shop may purchase a calibration fixture for its own use.

The turn tables and slip plates on the rack should be checked for dirt buildup and wear. Both of these can cause them to bind, which will cause incorrect settings. Also, never use the console as a workbench, even for small parts. Extra care should be paid to the alignment heads. They may fall while connecting and disconnecting them. Older machines have delicate electronics contained in the heads;

FIGURE 49-14 A computer-based wheel alignment machine.

FIGURE 49–15 A wheel alignment machine that relies on high-imaging cameras and targets to gather measurements.

they can be easily damaged. If the heads are dropped, they should be recalibrated before they are used again.

The heads on newer alignment machines **(Figure 49–15)** do not contain electronic parts. Rather, the heads serve as targets **(Figure 49–16)** for cameras mounted above the console **(Figure 49–17)**. Light from LEDs on the alignment machine is reflected back and picked up by the digital cameras. Damaged or dirty targets lose their reflectivity and the light may not be picked up by the cameras.

Turning Radius Gauges

Turning radius gauges measure how many degrees the front wheels are turned. They are commonly used to measure camber, caster, and toe-out on turns. Turning radius gauges (sometimes called turn tables) may be portable but are commonly found as part of an alignment rack. To use these gauges, the front wheels are centered on the gauge plates. Then the locking pins are removed to allow the plate to turn with the tires. As the tires are turned, a pointer will indicate how many degrees the tires have turned. To check toe-out on turns, turn one of the tires to 20 degrees. Then look at the gauge on the other tire.

Modern wheel alignment equipment may check toe-out-on-turns automatically when checking caster or there may be a separate test menu. When the wheels are turned, the sweep of the targets is used to check toe-out-on-turns.

FIGURE 49–16 These targets are similar to those shown in Figure 49–15 and work by reflecting light back up to digital cameras.

Alignment Machines

There are many varieties of alignment machines that have been used through the years. Some are equipped to measure alignment angles at all four wheels of the vehicle, and others measure the angles at only two wheels. Some alignment machines simply display the angle readings, whereas most current models give much more **(Figure 49–19)**, such as:

- A model-specific inspection screen with photos and illustrations
- Caster, camber, SAI, included angle, setback, and toe readings
- A printed analysis for the customer explaining what should be done
- Displays the required hand tools, special tools, and parts needed to make adjustments
- Photos and videos showing how to make the adjustment
- The steps required to correct the alignment, including:
  - The correct size and placement of shims (front and rear)
  - How much to turn an eccentric
  - How much to move an arm mounted in the slot
  - How much and in what direction to adjust the tie-rod
- Prints a summary and the results of the work

Normally an alignment rack is part of the alignment machine's package. The rack is best described as a limited-purpose vehicle hoist (lift) equipped with turning radius plates. Some alignment racks incorporate features such as powered locking and unlocking of turn plates and inflation stations for checking and setting tire pressure.

CUSTOMER CARE

Many of the alignment machines have printers that allow the customer to see a before-and-after picture of what the technician did. Along with these readings are the specifications. This is a great tool to gain a customer's confidence in your service, so offer him or her a copy when you have completed an alignment.

Two-Wheel Alignment

Two-wheel alignment equipment aligns the front wheels to the geometric centerline, assuming that the rear wheels are square with respect to the centerline. If this is true, this type of alignment produces satisfactory results. If not, steering and tracking might be a problem.

Four-Wheel Alignment

Four-wheel (or **total wheel) alignment** sets the alignment angles on all four wheels so they are positioned straight ahead with the steering wheel centered. The wheels and axles must also be parallel to one another and perpendicular to a common centerline. More than 85 percent of all new vehicles require that all four wheels be aligned.

Four-wheel alignment is the best approach in terms of both accuracy and completeness for wheel alignment because it references the front wheels to the rear wheels. The first step during an alignment is adjusting rear camber and toe or bringing the rear axle or wheels into square with the chassis. The front caster, camber, and toe settings can then be adjusted.

Performing an Alignment

All wheel alignment angles are interrelated. Regardless of the make of a car or the type of suspension, the same adjustment order—rear camber, rear toe, front caster, camber, toe—should be followed. Some MacPherson suspensions do not provide for caster or camber adjustments. However, there are some aftermarket kits that allow for these adjustments. Additionally, adjustment methods vary from model to model and, occasionally, even among different model years.

After the vehicle is properly placed on the rack and turn tables, vehicle information is input into the machine and the wheel units (heads) are installed. On some machines, the wheel units or heads must be compensated for wheel run-out. When compensation is complete, caster and toe-out-on-turns is checked and alignment measurements are displayed. Also displayed are the specifications for that vehicle. In addition to the normal alignment specifications, the machine may display asymmetric tolerances, different left- and right-side specifications, and cross specifications (the difference allowed between the left and right sides). Graphics and text on the screen show the technician where and how to make adjustments **(Figure 49–20)**. As the adjustments are made on the vehicle, the technician can observe the center block slide toward the target. When the block aligns with the target, the adjustment is within half the specified tolerance. A typical procedure for checking the alignment of all four wheels with a computerized alignment machine is shown in Photo Sequence 47.

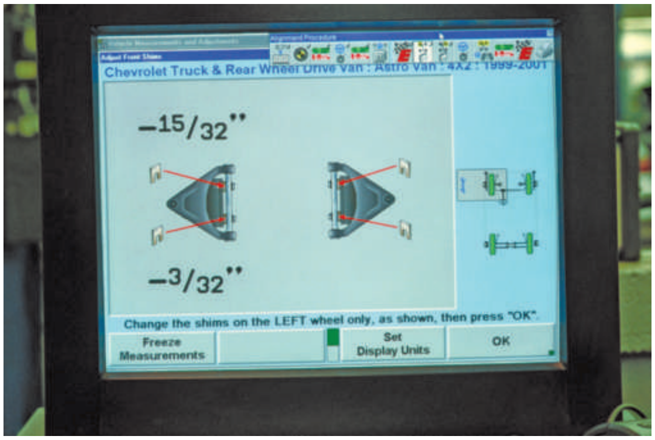

FIGURE 49–20 On many wheel alignment machines, the screen shows how and where to make adjustments.

Specifications

All angles and measurements should be set to the manufacturer's specifications. These specifications usually list a preferred angle for camber, caster, and toe. They are also listed with a minimum and maximum specification, sometimes listed as a plus or minus **(Figure 49–21)**. When making adjustments, you should attempt to achieve the preferred angle. If this is not possible, make sure the measurements are within the minimum and maximum range. If you cannot make an adjustment within that range, something is wrong and the suspension and frame should be careful checked.

In most cases, the bolts or nuts need to be loosened to make the necessary adjustments. Make sure that all of these are retightened to the required torque.

Performance TIP *If you want to improve the vehicle's handling, for the street only, you can do this by aligning the wheels to improve the tire's road contact, while staying within the manufacturer's acceptable ranges. To do this, set negative camber to the maximum allowable, the maximum positive caster, and the preferred toe settings.*

Rear-Wheel Camber Adjustments

Like front camber, rear camber affects both tire wear and handling. The ideal situation is to have zero running camber on all four wheels to keep the tread in full contact with the road for optimum traction and handling.

Camber is not a static angle. It changes as the suspension moves up and down. Camber also changes as the vehicle is loaded and the suspension sags under the weight.

To compensate for loading, some vehicles with independent rear suspension often call for a slight amount of positive camber. Other vehicles, particularly sports cars, tend to use negative camber. This enhances the handling abilities of the car. A collapsed or mislocated strut tower, bent strut, collapsed upper control arm bushing, bent upper control arm, sagging spring, or an overloaded suspension can cause the rear wheels to have negative camber. A bent spindle or strut or bowed lower control arm can cause too much positive camber. Even rigid rear axle housings in rear-wheel drive vehicles can become bowed by excessive torque, severe overloading, or road damage.

Caution! Before lifting the rear of a FWD vehicle, make sure you are using the correct lift point. Never jack on rear control arm rods or rear tie-rods. The weight of the vehicle may cause the parts to bend and result in misalignment of the rear wheels. Always lift the vehicle at the recommended lifting points.

Besides wearing the tires unevenly across the tread, uneven side-to-side camber (as when one wheel leans in and the other does not) creates a steering pull just like it does when the camber readings on the front wheels do not match. It is like leaning on a bicycle. A vehicle always pulls toward a wheel with the most positive camber. If the mismatch is at the rear wheels, the rear axle pulls toward the side with the greatest amount of positive camber. If the rear axle pulls to the right, the front of the car drifts to the left, and the result is a steering pull even though the front wheels may be perfectly aligned.

The methods used to adjust rear suspensions vary. On some semi-independent suspensions, camber and toe are adjusted by inserting different sizes of shims or a full contact shim between the rear spindle and the spindle mounting **(Figure 49–22)**. The shim thickness is changed between the top or bottom of the spindle to adjust camber. Many shims are now available that are round but have different thicknesses through their diameters. Most alignment computers can display exactly how to install a rear shim to set camber and toe at the same time.

On others, a camber adjustment can be made by installing a wedge spacer between the top of the knuckle and the strut. Many rear suspensions have

eccentric bolts and cams at the mounting points for the control and/or trailing arms **(Figure 49–23)**.

Remember that rear camber is adjusted first. Once the rear camber is set, rear toe is adjusted. Once the rear wheels are properly aligned, the thrust line should be parallel with the vehicle centerline and the front-wheel alignment checked and adjusted.

Rear Toe Rear toe, like front toe, is a critical tire wear angle. If toed-in or toed-out, the rear tires scuff just like the front ones. Either condition can also contribute to steering instability as well as reduced braking effectiveness. Keep this in mind with antilock brake systems.

Like camber, rear toe is not a static alignment angle. It changes as the suspension goes through jounce and rebound. It also changes in response to rolling resistance and the application of engine torque. With FWD vehicles, the front wheels tend to toe-in under power while the rear wheels toe-out in response to rolling resistance and suspension compliance. With RWD vehicles, the opposite happens, the front wheels toe-out while the rear wheels on an independent suspension try to toe-in as they push the vehicle ahead.

If rear toe is not within specifications, it affects tire wear and steering stability just as much as front toe. A total toe reading that is within specifications does not necessarily mean the wheels are properly aligned—especially when it comes to rear toe measurements. If one rear wheel is toed-in while the other is toed-out by an equal amount, total toe would be within specifications. However, the vehicle would have a steering pull because the rear wheels would not be parallel to center. The thrust line will also show as off, in this case.

FIGURE 49–23 An independent rear suspension may have eccentric cams at all of its control arms, one for camber adjustment and another for toe adjustment.

Remember, the ideal situation is to have all four wheels at zero running toe when the car is traveling down the road. This is especially true with antilock brakes, where improper toe can affect brakes; such a condition can affect brake balance when braking on slick or wet surfaces, causing the antilock brakes to cycle on and off to prevent a skid. Without antilock brakes, this condition may upset traction enough to cause an uncontrollable skid.

Rear toe may be adjusted by adjusting a tie-rod, similar to those found in the front steering linkage, by eccentric bolts, or by moving slotted control arms.

Thrust Line

If both rear wheels are square to one another and the rest of the vehicle, the thrust line is perpendicular to the rear axle and coincides with the vehicle's centerline. But if one or both rear wheels are toed in or out, or one is set back slightly with respect to the other, the thrust line is thrown off-center.

The thrust angle **(Figure 49–24)** is eliminated by aligning the rear axle with the geometric centerline of the vehicle and then adjusting the toe of the front wheels. This is normally done during a four-wheel alignment if the rear toe is adjustable. In most cases, doing this will also center the steering wheel. If the thrust angle is ignored and front toe is set to the geometric centerline, the steering wheel will be off-center.

Four-wheel-alignment machines check the toe at each wheel. An incorrect thrust line may be caused by unequal amounts of toe at the rear wheels. Therefore, each rear wheel should be adjusted to the same toe specification. On most FWD vehicles and those with adjustable rear toe, this can be easily done by using the factory-provided toe adjustments, by placing toe/camber shims between the rear spindles and axle, or by using eccentric bushing kits.

On RWD vehicles that have a solid rear axle, changing rear toe is not as easy **(Figure 49–25)**. Sometimes the floor pan or frame rails are misaligned from the factory or from collision damage. Short of straightening the chassis on a collision bench to restore the correct control arm or spring-mount geometry, the only other options are to try some type of offset trailing arm bushing with the coil springs, or to reposition the spring shackles or U-bolts with leaf springs.

If rear toe cannot be easily changed, the next best alternative is to align the front wheels to the rear axle thrust line rather than the vehicle centerline. Doing this puts the steering wheel back on center and eliminates the steering pull—but it does not eliminate tracking.

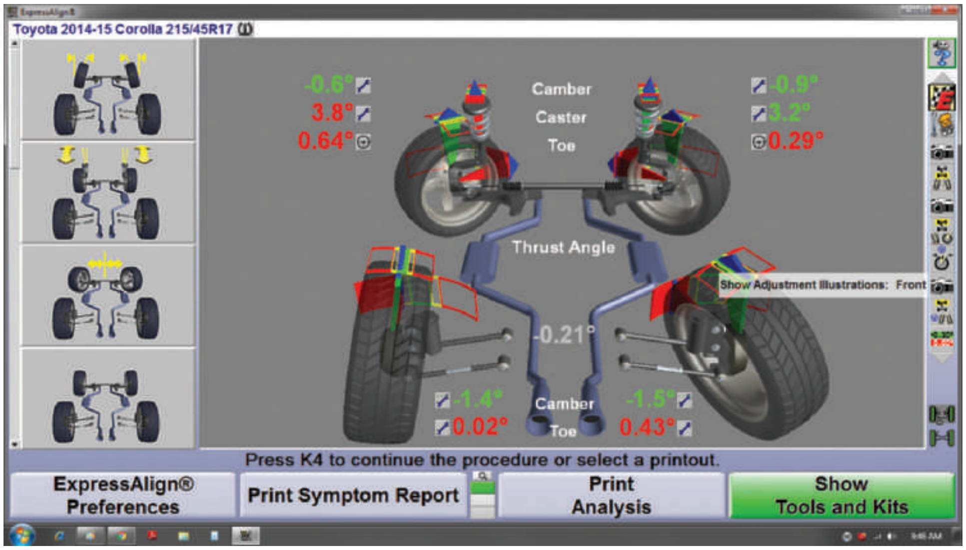

FIGURE 49–24 The thrust angle is the angle between the geometric centerline of the vehicle and the thrust line.

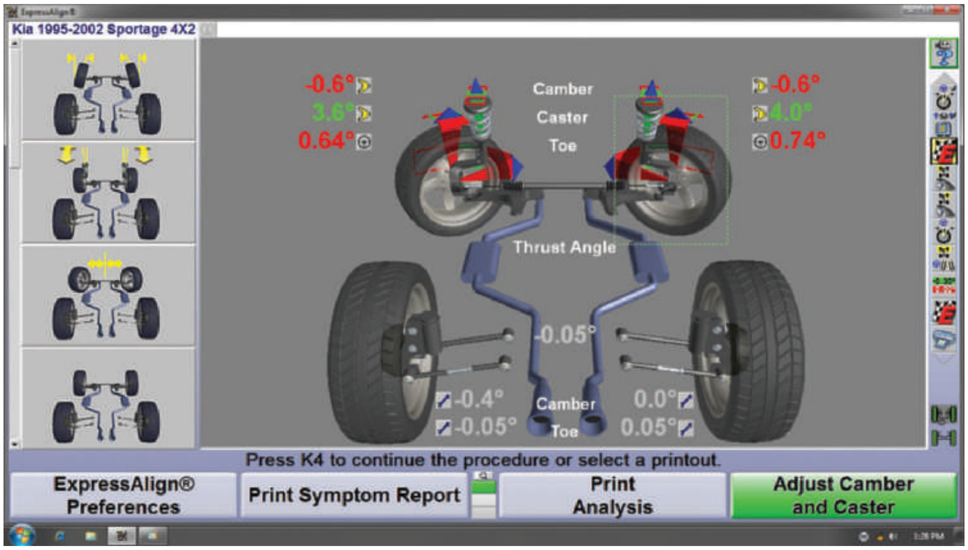

FIGURE 49–25 Thrust angle and a vehicle with non-adjustable rear toe.

Caster/Camber Adjustment

Caster affects steering stability and steering wheel returnability. Zero (0) caster is present when the upper ball joint or top strut bearing and lower ball joint are in the same plane as viewed from the side of the vehicle. Positive caster exists when the upper ball joint or top strut bearing is toward the rear of the vehicle in relationship to the lower ball joint. When the upper ball joint or top strut bearing is toward the front of the vehicle in relationship to the lower ball joint, negative caster is present. If the caster at both wheels is not equal, the vehicle will tend to drift toward the side with the lowest caster.

Camber is the inward or outward tilt of the top of the wheel. Adjusting camber centers the vehicle's weight on the tire. Proper camber adjustment minimizes tire wear. Zero (0) camber is present when the wheel is at a perfectly vertical position. The tires have positive camber when the top of the tire is tilted out, or away from the engine. When the top of the tire is tilted in, there is negative camber. Incorrect camber will cause excessive stress and wear on suspension parts. Too much negative camber will cause wear on the inside tread of the tire, whereas too much positive camber will cause tire wear on the outside tread. If camber is not the same on both wheels, the vehicle will pull toward the side with the most positive camber.

SHOP TALK

Sometimes it is impossible to adjust the camber to specifications. When this happens, suspect a poorly seated wheel hub and hearings, a bent frame, weak springs, a bent steering knuckle, or a bent control arm.

Adjusting for Road Crown To compensate for road crown, most alignment specifications allow for slightly different caster and camber specifications on each side of the vehicle. This difference causes the vehicle to naturally pull slightly to the left to overcome the natural pull of the road to the right.

Typically, specifications call for slightly more negative camber (approximately ¼ degree) on the right side of the vehicle. Or the caster on the left should be set with slightly more negative caster (approximately ¼ degree).

Adjusting Caster and Camber

Several methods are used to adjust caster and camber; always check the service information to determine how the alignment angles can be changed. Most current wheel alignment machines feature illustrations, pictures, or videos of what should happen and where.

Camber on nearly all front suspensions is adjustable, although installing special bolts or making modifications to the strut or knuckle may be needed. On strut-equipped vehicles, camber can be adjusted by moving the top of the strut mount or by adjusting an eccentric bolt located where the strut attaches to the steering knuckle. Caster is adjustable on some strut-equipped vehicles. This is done by again moving the top of the strut. Typically, there is no provision for adjusting caster. Vehicles that have no simple means for adjusting camber or caster require the installation of special kits from the aftermarket to obtain the correct angles. These kits basically contain an adjustable strut mount that permits the top of the strut to move front to back and left to right.

On other vehicles, the upper or lower control arm is used to adjust camber and caster. This is done by adding or removing shims between the control arm and the frame or by rotating an eccentric shaft or eccentric washers. Two bolts attach the control arm to the frame. An equal amount of shims is placed behind or in front of both bolts to correct camber. To gain more negative camber, the lower control arm must be moved outward or the upper arm moved inward. The opposite is true for gaining positive camber.

Caster is adjustable on all vehicles with an upper and a lower control arm. This is done by rotating an eccentric bushing at one of the pivot points for the control arm or adding or subtracting shims between a control arm and the frame.

SHOP TALK

When the vehicle has been aligned to compensate for road crown, it will pull to the left when it is traveling on a flat road or on a road that is angled to the left.

Shims Many cars use shims for adjusting caster and camber **(Figure 49–26)**. The shims can be located between the control arm pivot shaft and the inside of the frame. Both caster and camber can be adjusted in one operation requiring the loosening of the shim bolts just once. Caster is changed by adding or subtracting shims from one end of the pivot shaft only. Then, camber is adjusted by adding or subtracting an equal amount of shims from the front and rear bolts. This procedure allows camber to change without affecting the caster setting.

Some cars use shims located between the control arm pivot shaft and the outside of the frame.

SHOP TALK

A feature of some alignment machines makes the job of adjusting camber and caster much easier and quicker. The feature has many names; the most common one is “jack and hold.” This allows for caster and camber adjustments with the wheels off the ground. The advantage here is simply more room to work, and the vehicle’s weight is off the adjusting points. Although camber and caster will change when the wheel is lifted, the machine will display the reading before the wheel was raised. This allows you to make adjustments and monitor them just as if the vehicle was sitting flat. Of course all measurements should be verified after the wheels are back on the ground.

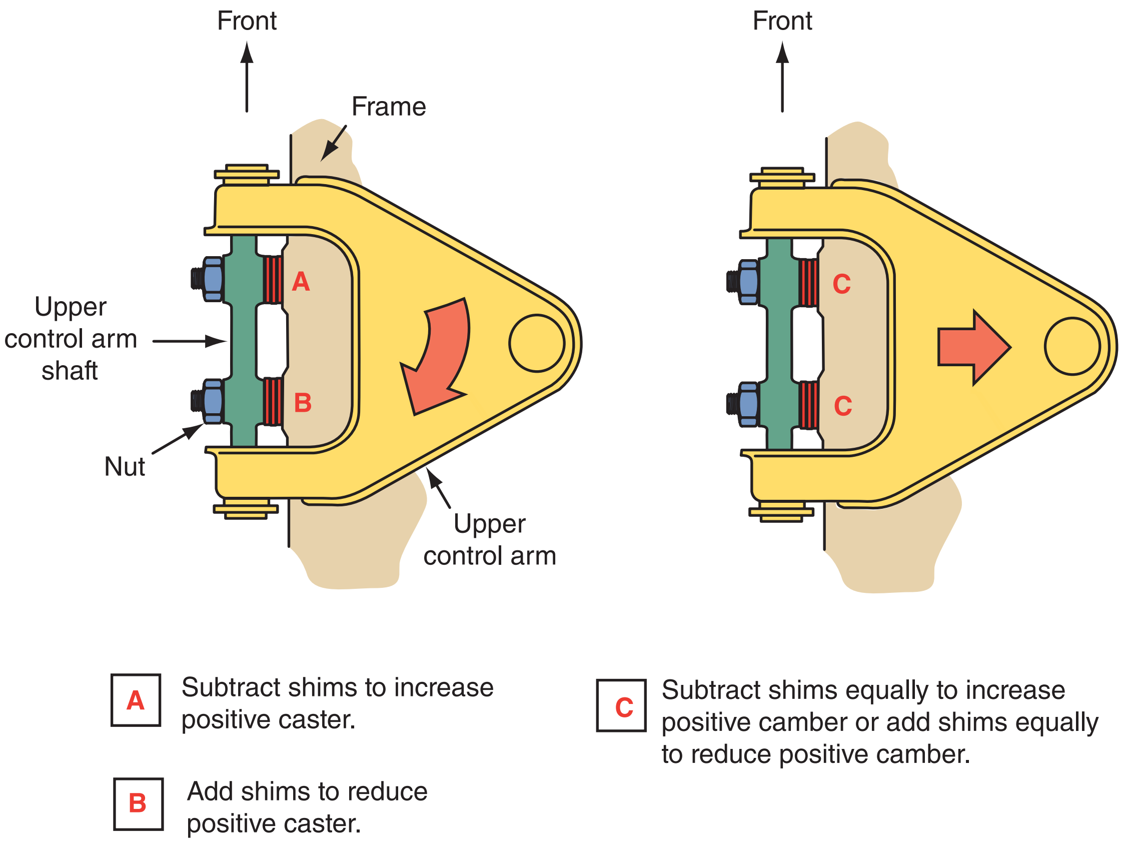

FIGURE 49–26 Adding and subtracting shims between the control arm and the frame will change caster and camber.

The adjustment procedure is the same as just described. Always look at the shim arrangements to determine the desired direction of change before loosening the bolts.

Eccentrics and Shims Eccentrics and shims are used on some vehicles to adjust caster and camber. In some designs, an eccentric bolt and cam on the upper control arm adjust both caster and camber. To adjust, the nuts on the upper control arm are loosened first. Then, one eccentric bolt at a time is turned to set caster. Both bolts are turned equally to set camber.

The eccentric bolt and cam assembly **(Figure 49–27)** can be located on the inner lower or upper control arm. Unlike other designs, camber is adjusted first. Some car models have a camber eccentric between the steering knuckle and the upper control arm. The camber eccentric is rotated to set camber **(Figure 49–28)**. Caster is set with an adjustable strut rod.

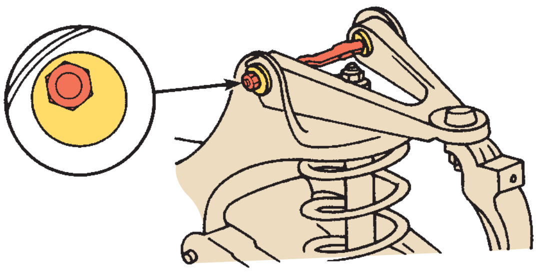

FIGURE 49–27 Eccentric bolt and cam, shown on an upper control arm.

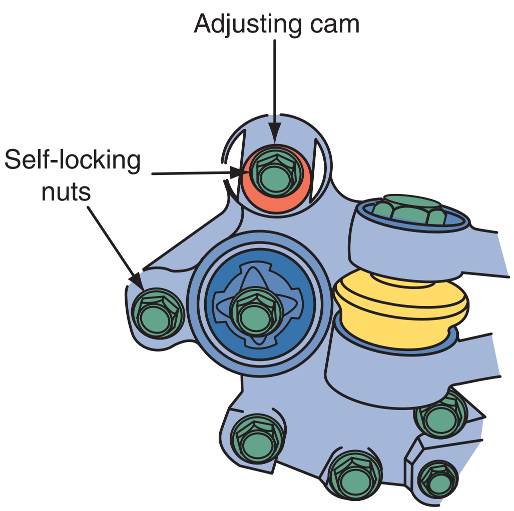

FIGURE 49–28 Graduated cam for adjusting camber.

Slotted Frame The slotted frame adjustment has slotted holes under the control arm inner shaft that allow the shaft to be repositioned to the correct caster and camber settings. Caster and camber adjusting tools help in making adjustments. One end of the shaft is moved for caster adjustment. Both ends of the shaft are moved for camber adjustment. Turning a nut on one end of the rod changes its length and adjusts caster. Camber is set by an eccentric at the inner end of the lower control arm, or by a camber eccentric in the steering knuckle of the upper support arm, as described earlier.

Ball Joint Stud Bushings Some suspension systems have an eccentric bushing at the top of the steering knuckle. This bushing can be used to adjust camber and camber. The bore for the ball joint stud through the bushing is off-center. Rotating the bushing moves the wheel's geometry. If the correct alignment cannot be attained by rotating the bushing, replacement bushings are available. You will need to obtain a bushing that changes the caster and/or camber specific amounts.

MacPherson Suspension Adjustments

Caster/camber adjustments are made only on certain models with MacPherson suspensions. There are two general OEM procedures for doing this, although aftermarket kit adapters are available for some models. Service information must be consulted for an accurate listing of models on which adjustments can be made.

In one version, a cam bolt at the base of the strut assembly is used to adjust camber **(Figure 49–29)**.

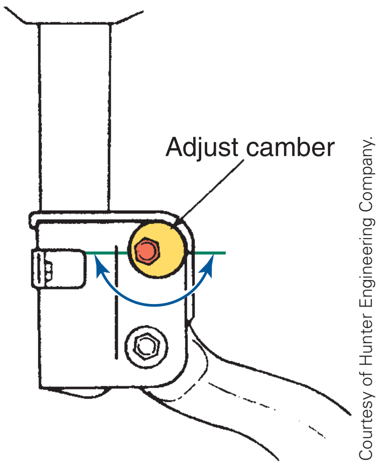

FIGURE 49–29 Some MacPherson suspensions use cam bolts at the connection to the steering knuckle for camber adjustments.

On different models, this bolt can be either the upper or the lower of the two bolts connecting the strut assembly to the steering knuckle. Both bolts must be loosened to make the adjustment, and the wheel assembly must be centered. Turn the cam bolt to reach the correct alignment, then retighten the bolts to the appropriate torque specifications. There is no caster adjustment on this version.

To change the camber on some struts, the mounting holes in the strut where it attaches to the steering knuckle are enlarged. Extending the holes allows the strut to move relative to the knuckle, changing the camber.

In the other form of kit adapter, both caster and camber are adjustable at the strut upper mount. Slots in the mounting plate permit the strut assembly to be shifted to reach the alignment specifications. To adjust caster, loosen the three locknuts on the mounting studs and relocate the plate. Do not remove the nuts **(Figure 49–30)**. Loosen the center locknut and slide it toward or away from the engine as needed to adjust camber correctly.

While caster cannot be adjusted on many MacPherson strut front suspensions, camber can be adjusted. The camber is such that, although it is locked in place with a pop rivet, it can be adjusted by removing the rivet from the camber plate and loosening the three nuts that hold the plate to the body apron **(Figure 49–31)**. Camber is changed by moving the top of the shock strut to the position in which the desired camber setting is achieved. The nuts are then tightened to specifications. (It is not necessary to install a new pop rivet.)

Toe Adjustment

Toe is the last alignment angle to be set. The same procedure is followed on all vehicles, except those with bonded ball stud sockets. Correct toe will minimize tire wear and rolling friction.

To adjust toe, start by being sure the steering wheel is centered **(Figure 49–32)** when the front wheels point straight ahead. Using a steering wheel holder, secure the steering wheel in that position. Many steering wheel holders are installed between the steering wheel and the top of the front seat. Then loosen the retaining bolts on the tie-rod adjusting sleeves. Turn the sleeves to move the tie-rod ends **(Figure 49–33)**.

Some manufacturers of alignment machines recommend that a steering wheel holder not be used. Instead, a steering wheel angle gauge is used to ensure that the steering wheel is centered.

On many rack and pinion systems, the tie-rod locknut must be loosened and the tie rod rotated to

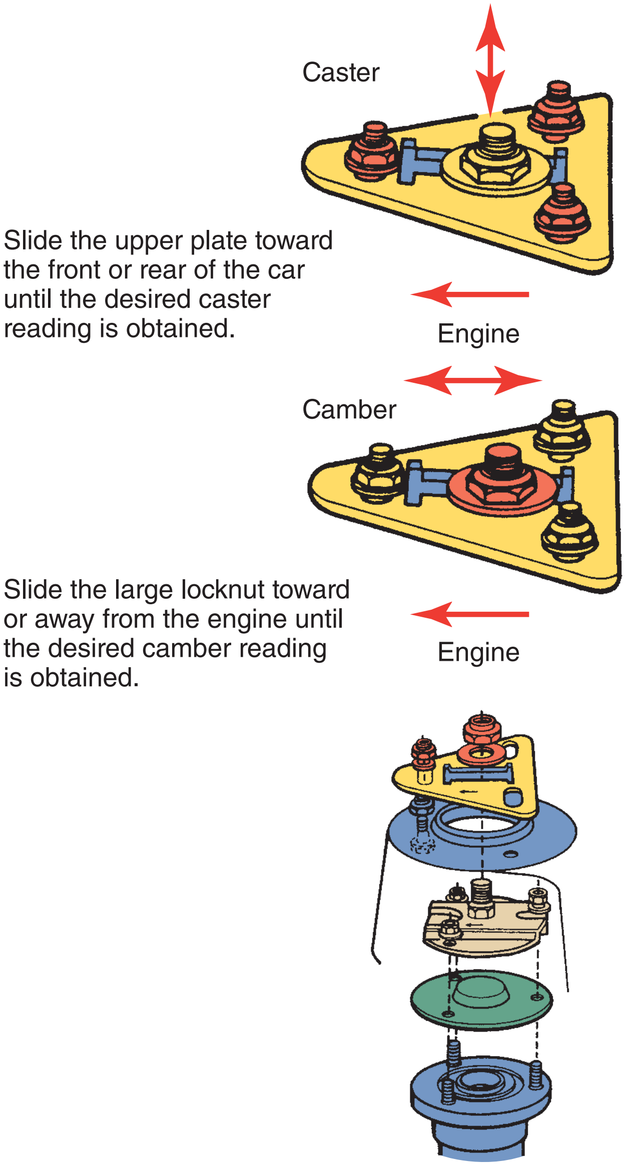

FIGURE 49-30 Caster and camber adjustment of locknuts.

adjust toe at each wheel **(Figure 49–34).** Before rotating the tie-rod, the small outer bellows clamp must be loosened to prevent the boot from twisting.

Other rack and pinion tie-rod ends have internal threads and a threaded adjuster. One end of the adjuster has right-hand threads, the other has left-hand threads. As the adjuster is turned, it changes the overall length of the tie-rod, thereby changing toe.

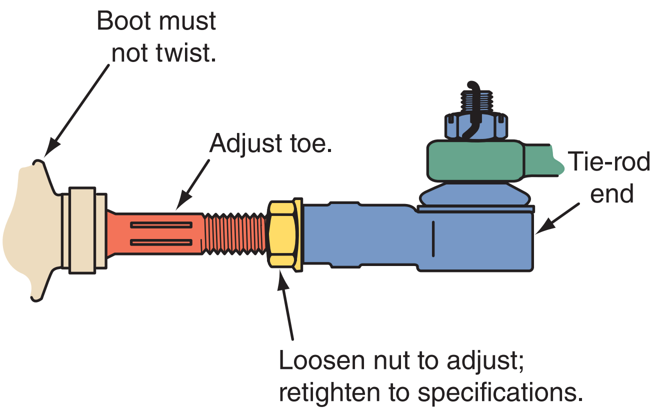

FIGURE 49-34 Rotating the tie-rod to adjust the toe on a rack and pinion steering gear.

> **SHOP TALK** If you are unable to adjust the toe to specifications, check for a bent lower control arm, worn or stripped tie-rod sleeves, a bent tie-rod, or a bent frame.

An ideal toe condition is both wheels exactly straight ahead, which would minimize tire wear. This, however, is not possible because of the many factors affecting alignment. As a result of these numerous conditions dealing with both tire wear and handling, all suspensions are designed with a slight toe-in or toe-out.

Any misalignment of the steering linkage pivot point or control arm pivot point (such as the center link or rack and pinion out of place) causes the condition known as **toe-change**. Toe-change involves turning the wheels from their straight-ahead position as the suspension moves up and down.

The change might be only one wheel, both wheels in the same direction, or both wheels in the opposite direction. Regardless of the condition, any change of one or more wheels is a toe-change condition. The results are tire wear and a hard-to-handle vehicle. The poor handling effects can get to the point that the vehicle is dangerous to drive.

Toe change is not a specification; it is a condition in which the toe setting constantly varies. It must be determined by equipment or a method that measures individual wheel toe at all suspension heights. There must be a change in suspension heights for any changes to occur.

Lightweight front-wheel drive vehicles can be affected greatly by toe-change. With these vehicles, the front wheels are no longer being pushed. They actually pull the vehicle forward and, as a result, if the wheels are not maintaining a straight-ahead position, they affect directional control. Adverse road conditions, such as wet or icy conditions, can also increase the handling effects created by toe-change in the front-wheel drive car.

Setback

Setback is a condition when one wheel on an axle is set behind the other **(Figure 49–35)**. This means the distance between the centers of the tires on one side of the vehicle will be different than on the other side. Like the thrust angle, setback will cause an off-centered steering wheel. Most alignment machines measure setback. Excessive setback is evident by a reading of more than ¼ inch (6.35 mm). Setback is typically caused by a bent suspension part, problems with the upper strut mount, or a misaligned lower control arm. It can also be caused by a misaligned front cradle **(Figure 49–36)**. If the setback is slight, the difference will be compensated during a good four-wheel alignment.

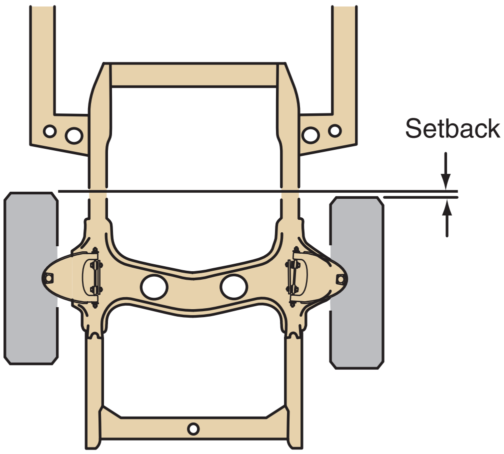

FIGURE 49-35 Setback is a condition when one wheel on an axle is set behind the other.

FIGURE 49-36 Collision damage or dropping the powertrain can cause cradle misalignment concerns.

Four-Wheel Drive Vehicle Alignment

With front-wheel drive and AWD vehicles, the front wheels are also driving wheels. As the front wheels pull the vehicle, the wheels tend to toe-in when torque is applied. To offset this tendency, the front wheels usually need less static toe-in to produce zero running toe. In fact, the preferred toe alignment specifications in this instance can be zero to slightly toed-out ($^1/_{16}$-inch [1.5 mm]) toe-out.

It is important to note that when the front wheels of a part-time 4WD system are freewheeling, they behave the same as the front wheels in a rear-wheel drive vehicle. That is, they roll rather than pull. The wheels tend to toe-out, so the static toe setting would have to toe-in to achieve zero running toe when driving in the two-wheel mode.

The tires suffer in proportion to toe misalignment. For a tire that is only ⅛-inch (3 mm) off (¼ degree), the tire is scrubbed sideways 12 feet (3.6 meters) for every mile traveled. That may not sound like much, but 12 feet (3.6 meters) of sideways scrub every mile can cut a tire's life in half.

If rapid tire wear seems to be the problem, look for the telltale feathered wear pattern **(Figure 49–37)**. If the wheels are running toe-in, the feathered wear pattern leaves sharp edges on the inside edges of the tread. If the wheels are running toe-out, the sharp edges are toward the outside of the tread. It is usually easier to feel the feathered wear pattern than to see it. To tell which way the wear pattern runs, rub your fingers sideways across the tread.

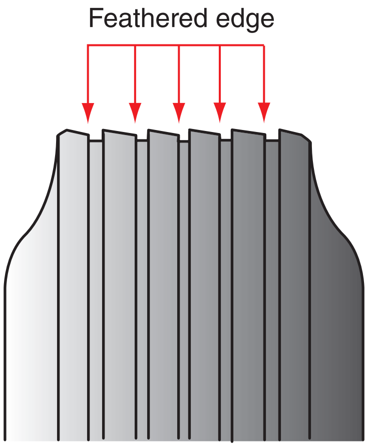

FIGURE 49–37 Incorrect toe can cause a feathered wear pattern.

On most heavy-duty 4WD vehicles, caster is not adjustable. After-market companies do provide caster adjustment kits for some pickups. These kits may contain shims or eccentric cam and bolt. For some pickups, the aftermarket cam kit will also provide for camber adjustments.

On other 4WD vehicles, camber is adjusted by installing adjustment shims between the spindle and the steering knuckle or by installing and/or adjusting an eccentric bushing at the upper ball joint. Most aftermarket parts manufacturers have camber adjustment shims available in various thicknesses and diameters. Never stack the shims. Only one shim per side should be used.

Steering Angle Sensor Calibration

Cars and light trucks that have electric power steering assist and/or vehicle stability control use sensors in the steering column or rack to measure steering shaft angle and torque. When performing an alignment or after work is performed on the steering system, these sensors may require calibration. This includes the removal, replacement or reinstallation of any steering component.

Sensor recalibration procedures vary from relatively simple to requiring a factory scan tool to access the system. Refer to the manufacturer's service information for procedures specific to the vehicle being aligned. Newer alignment machines can alert you to if a vehicle needs calibration **(Figure 49–38)**. The alignment machine may also have the ability to recalibrate the sensor by connecting to the DLC. Some vehicles do not require connecting to the on-board computer system. If the sensor is not recalibrated after an alignment, steering pull, return, and inconsistent effort issues can result.

SUMMARY

- Caster is the angle of the steering axis of a wheel from the vertical, as viewed from the side of the vehicle. Tilting the wheel forward is negative caster. Tilting backward is positive.
- Camber is the angle represented by the tilt of either the front or rear wheels inward or outward from the vertical as viewed from the front of the car.
- Toe is the distance comparison between the leading edge and trailing edge of the front tires. If the edge distance is less, then there is toe-in. If it is greater, there is toe-out.
- The difference of rear toe from the geometric centerline of the vehicle is called the thrust angle. The vehicle tends to travel in the direction of the thrust line, rather than straight ahead.
- Steering axis inclination (SAI) angles locate the vehicle weight to the inside or outside of the vertical centerline of the tire. The SAI is the angle between the true vertical and a line drawn between the steering pivots as viewed from the front of the vehicle.
- Turning radius or cornering angle is the amount of toe-out present on turns.
- In correct tracking, all suspensions and wheels are in their correct locations and conditions and are aligned so that the rear wheels follow directly behind the front wheels while moving in a straight line.
- It is important to remember that approximately 85 percent of today's vehicles not only undergo front-end alignment but require rear-wheel alignment as well.
- The primary objective of four-wheel or total-wheel alignment, whether front or rear drive, solid axle, or independent rear suspension, is to align all four wheels so the vehicle drives and tracks straight with the steering wheel centered. To accomplish this, the wheels must be parallel to one another and perpendicular to a common centerline.

It is commonly believed that the purpose of a brake system is to slow or halt the motion of a vehicle. However, that is really not true. The friction of the tires against the road is what slows down and stops a vehicle. The brake system slows or stops the rotation of the wheels. This is a minor point but one that extends the responsibility for braking to the tires as well as the brake system.

The brake system converts the momentum of the vehicle into heat by slowing and stopping the vehicle's wheels. This is done by causing friction at the wheels. The application of the friction units is controlled by a hydraulic system. This chapter looks at the basics of all brake systems and gives a detailed look at the hydraulic systems required to stop a vehicle.

GO TO Chapter 3 for a detailed discussion on friction and its effects.

Friction

There are two basic types of friction that explain how brake systems work: kinetic, or moving, and static, or stationary **(Figure 50–1)**. The amount of friction, or resistance to movement, depends on the type of materials in contact, the smoothness of their rubbing surfaces, and the pressure holding them together (often gravity or weight). Friction always converts moving, or kinetic, energy into heat. The greater the friction between two moving surfaces, the greater the amount of heat produced.

As the brakes on a moving automobile are applied, rough-textured pads or shoes are pressed against rotating parts of the vehicle—either rotors (discs) or drums. The kinetic energy, or momentum, of the vehicle is then converted into heat energy by the kinetic friction of the rubbing surfaces and the car or truck slows down.

When the vehicle comes to a stop, it is held in place by **static friction**. The friction between the surfaces of the brakes and between the tires and the road resists any movement.

Factors Governing Braking

Four basic factors determine the braking power of a system. The first three factors govern the generation of friction: pressure or force against the friction materials, coefficient of friction, and frictional contact surface. The fourth factor is a result of friction. It is heat or, more precisely, heat dissipation.

An additional factor—weight transfer—influences how well a vehicle will stop when the brakes are applied. When the brakes are applied while the vehicle is moving forward, the weight of the vehicle shifts forward. This causes the front of the vehicle to drop or "nose dive." It also means that the front brakes will need the most stopping power. If the vehicle is overloaded or if the front suspension is weak, more weight will be thrown forward and the brakes will need to work harder.

Pressure The amount of friction generated between moving surfaces in contact with each other depends

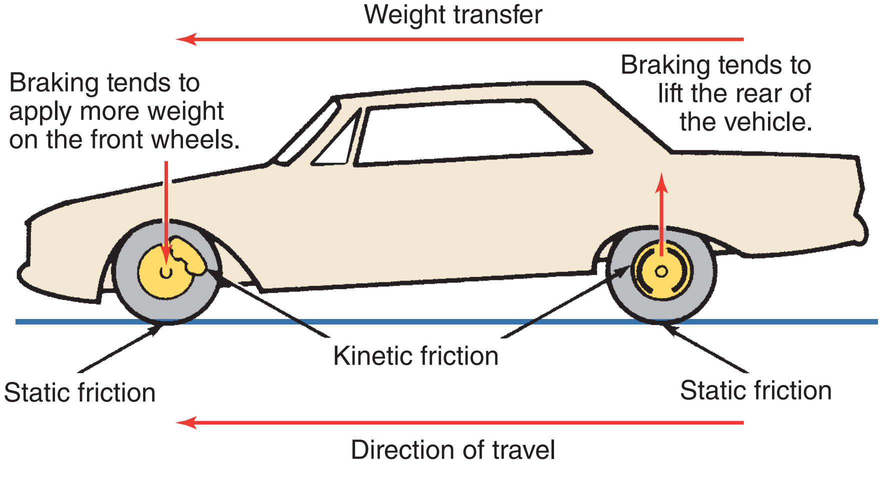

FIGURE 50–1 Braking action creates kinetic friction in the brakes and static friction between the tire and road to slow the vehicle. When brakes are applied, the vehicle's weight is transferred to the front wheels and is unloaded on the rear wheels.

in part on the pressure exerted on the surfaces. For example, if you slowly increase the downward pressure on the palm of your hand as you move it across a desk, you will feel a gradual increase in friction.

In a brake system, hydraulic systems provide application pressure. Hydraulic force is used to move brake pads or brake shoes against spinning rotors or drums mounted to the wheels. The amount of pressure is determined by the pressure on the brake pedal and the design of the brake system.

Coefficient of Friction The amount of friction generated between two surfaces is expressed as a **coefficient of friction (COF)**. The COF is determined by dividing the force required to pull an object across a surface by the weight of the object **(Figure 50–2)**. For example, if it requires 100 pounds (455 N) of pull to slide a 100-pound (45.4 kg) metal part across a concrete floor, the COF is 100 ÷ 100 or 1. To pull a 100-pound (45.4 kg) block of ice across the same surface may require only 2 pounds (9 N) of pull. The COF then would be only 0.02.

As it applies to automotive brakes, the COF expresses the frictional relationship between pads and rotors or shoes and drums. The required COF depends on the vehicle and other factors and is carefully chosen by the manufacturer to ensure safe and reliable braking. Therefore, when replacing pads or shoes, it is important to use replacement parts with similar COF. If, for example, the COF is too high, the brakes will be too sticky to stop the car smoothly. Premature wheel lockup or grabbing would result. If the coefficient is too low, the friction material tends to slide over the surface of the drum or rotor rather than slowing it down. Most automotive friction materials are engineered with a COF of between 0.25 and 0.55.

Frictional Contact Surface The third factor is the amount of surface area that is in contact. Simply put, bigger brakes stop a car more quickly than smaller brakes used on the same car. For the most part, the vehicle's weight and potential speed determines the size of the friction surface areas. Also, the greater the surface areas of the wheel brake units, the faster heat can be dissipated.

Heat Dissipation Any braking system must be able to effectively handle the heat created by friction within the system. The tremendous heat created by the rubbing brake surfaces must be conducted away from the pad and rotor (or shoe and drum) and be absorbed by the air. Brakes that do not effectively dissipate heat experience brake fade during hard, continuous braking.

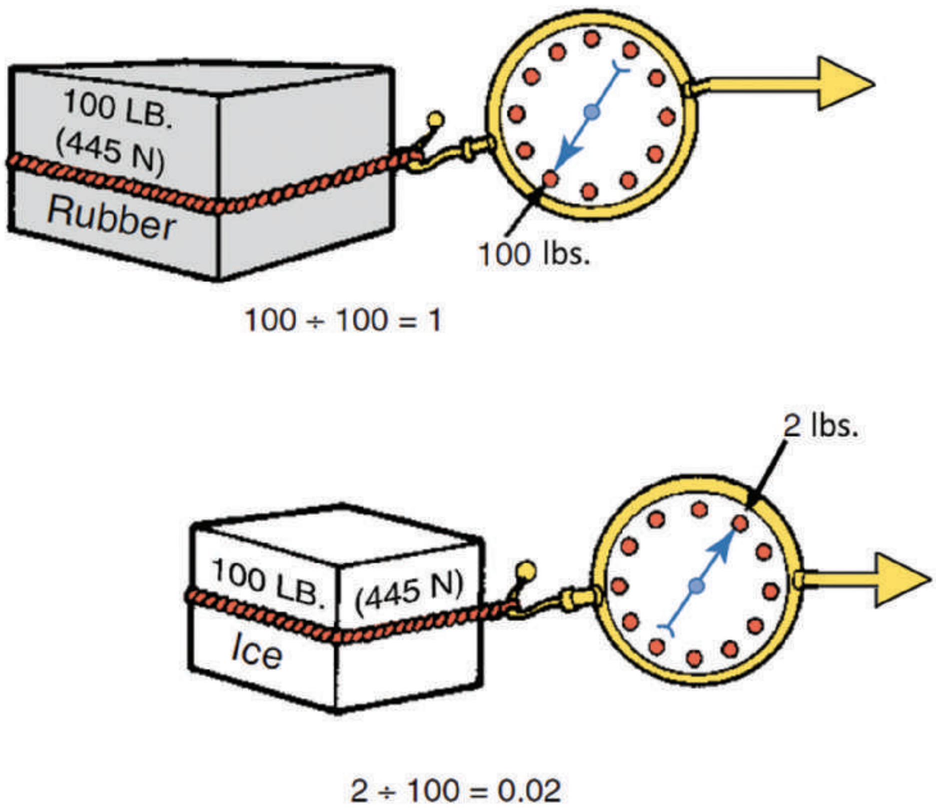

FIGURE 50–2 Coefficient of friction is equal to the pounds of pull divided by the weight of the object.

Brake fade is a condition where the stopping power of the brakes has been drastically reduced. This is commonly caused by excessive heat buildup. With brake fade, the brake pedal seems normal but there is reduced stopping ability. Brake fade may become worse as heat builds up; this may be due to outgassing. As the shoes or pads become extremely hot, they can generate a gas. This gas can become an air bearing between the frictional material and the rotor or drum. Rather than clamp on the wheel brake, the friction elements will slip on the air (gas buildup). Fade can also be caused by overheating the brake fluid because gases form in the fluid.

The friction materials must be able to dissipate heat and the system must be designed to allow the material to get rid of its heat. This may be done by allowing ample airflow past the brake units. Another way is to ventilate the rotors. Ventilated rotors have internal vanes that move the hot air from the disc to the outside **(Figure 50–3)**. Some rotors are cross-drilled or slotted. Both of these designs allow the rotor to run cooler and reduce the chances of gas buildup.

Heat can also cause the linings of the pads and shoes to become glazed and harden the rotor and drum. Therefore, the COF is reduced and excessive

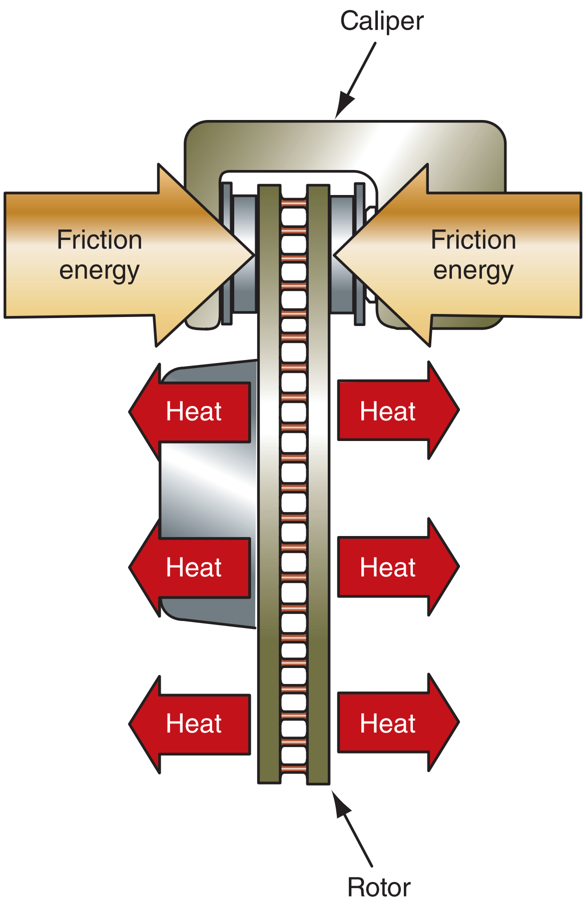

FIGURE 50–3 Heat generated during braking is dissipated as air moves through the rotor.

foot pressure must be applied to the brake pedal to produce the desired braking effect.

Brake Lining Friction Materials

Brake linings are made up relatively soft but tough and heat-resistant material with a high coefficient of friction. The lining is typically attached to a metal backing with rivets or high-temperature adhesives. For many decades, asbestos was the standard brake lining material. It offers good friction qualities, long wear, and low noise. But new materials are being used because of the health hazards of breathing asbestos dust. Asbestos has not been used in brake linings or pads since 2003. Many different materials are used as lining material and the type of lining is defined by its composition. Each type has different heat dissipation, fade resistance, rotor wear, noise generation, and braking force characteristics.

Nonasbestos Organic **Nonasbestos organic (NAO)** linings are installed on many vehicles by the OEM. Organic linings are made of nonmetallic fibers bonded together to form a composite material. Today's organic brake linings contain the following types of materials:

- *Friction materials and friction modifiers.* Some common examples of these are graphite, powdered metals, and even nut shells.
- *Fillers.* Fillers are secondary materials added for noise reduction, heat transfer, and other purposes.
- *Binders.* Binders are glues that hold the other materials together.
- *Curing agents.* These accelerate the chemical reaction of the binders and other materials.

Organic linings have a high COF, and they are economical, quiet, wear slowly, and are only mildly abrasive to rotors and drums. However, organic linings fade more quickly than other materials and do not operate well at high temperatures. High-temperature organic linings are available for high-performance use but they do not work as well at low temperatures. They also wear faster than regular organic linings.

Metallic Linings Fully metallic materials were used for many years in racing. **Metallic lining** is made of powdered metal that is formed into blocks by heat and pressure. These materials provide excellent resistance to brake fade but require high brake pedal pressure; they create the most wear on rotors and drums. Metallic linings work very poorly until they are fully warmed. Improved high-temperature organic linings

and semimetallic materials have made metallic linings almost obsolete for late-model automotive use. Metallic linings are also extremely noisy, which is something that must be considered by customers when choosing the type of brake lining to install on their vehicle.

Semimetallic Linings Semimetallic materials are made of a mixture of organic or synthetic fibers and certain metals molded together. **Semimetallic linings** are harder and more fade resistant than organic materials but require higher brake pedal effort.

Most semimetallic linings contain about 50 percent iron and steel fibers. Copper also has been used in some semimetallic linings and, in smaller amounts, in organic linings. Concerns about copper contamination of the nation's water systems has led to its reduced use in brake linings, however.

Semimetallic linings operate best above 200 °F (93.3 °C) and actually must be warmed up to bring them into full efficiency. Consequently, they are typically less efficient than organic linings at low temperatures.

Semimetallic linings were sometimes used on older heavy or high-performance vehicles with four-wheel drum brakes. Currently, semimetallic linings are used only on the front disc brakes of passenger cars and light trucks. The lighter braking loads on rear brakes, particularly on FWD cars, may never heat semimetallic linings to their required operating efficiency. Semimetallic linings also have a lower static COF than organic linings, which makes them less efficient with parking brakes.

Synthetic Linings The goals of improved braking performance and the disadvantages of the other lining materials have led to the development of **synthetic lining** materials. They are classified as synthetic because they are made of nonorganic, nonmetallic, and nonasbestos materials. Two types of synthetic materials are commonly used as brake linings for drum brakes: fiberglass and **aramid fibers**.

Fiberglass was introduced as a brake lining material to help eliminate asbestos. Like asbestos, it has good heat resistance, good COF, and excellent structural strength. The disadvantages of fiberglass are its higher cost and its reduced friction at very high temperatures. Overall, fiberglass linings perform similarly to organic linings and are used primarily in rear drum brakes.

Aramid fibers are a family of synthetic materials that are five times stronger than steel, pound for pound, but weigh little more than half what an equal volume of fiberglass weighs. Friction materials made with aramid fibers are made similarly to organic and fiberglass linings. Aramid fibers have a COF similar to semimetallic linings when cold and close to that of organic linings when hot. Overall, the performance of aramid linings is somewhere between organic and semimetallic materials but with much better wear resistance and longevity than organic materials.

Ceramic Ceramic linings are found on many FWD vehicles, because they have high heat resistance. Most ceramic pads are made of a ceramic material mixed with copper fibers. These pads are quiet and produce little dust, making them popular as both OE and as aftermarket replacement parts.

Carbon-Metallic/Ceramic Carbon-metallic pads are often used on high-performance cars due to their good COF and high heat resistance. Carbon linings are also able to withstand very high temperatures without causing brake fade. A few aftermarket companies offer linings made of carbon, Kevlar, and various other materials. These also have ceramic heat shields that reduce the amount of heat that can transfer from the linings to the rest of the brake system. Some high-performance cars are fitted with carbon-ceramic pads. These pads are comprised of a ceramic composite of carbon fiber reinforced with silicon carbide. These pads offer excellent braking performance and are extremely lightweight. They also provide a consistent COF through a wide range of temperature and weather conditions.

Low-Copper Compliance Pads

Since 2014, California and Washington States require that brake pad manufacturers phase out linings with copper and other hazardous materials. This is due to the brake dust material contaminating water sources and harming aquatic life.

There are three levels of low-copper pads:

- Level A pads comply with requirements for cadmium, chromium, lead, mercury, and asbestos.
- Level B pads meet Level A requirements and copper content must be reduced to less than 5 percent of the pad material by 2021.
- Level N pads will have less than 0.5 percent total copper by 2025.

Principles of Hydraulic Brake Systems

A hydraulic system **(Figure 50–4)** uses brake fluid to transfer pressure from the brake pedal to the pads or shoes. This transfer of pressure is reliable and consistent because liquids are not compressible. That is,

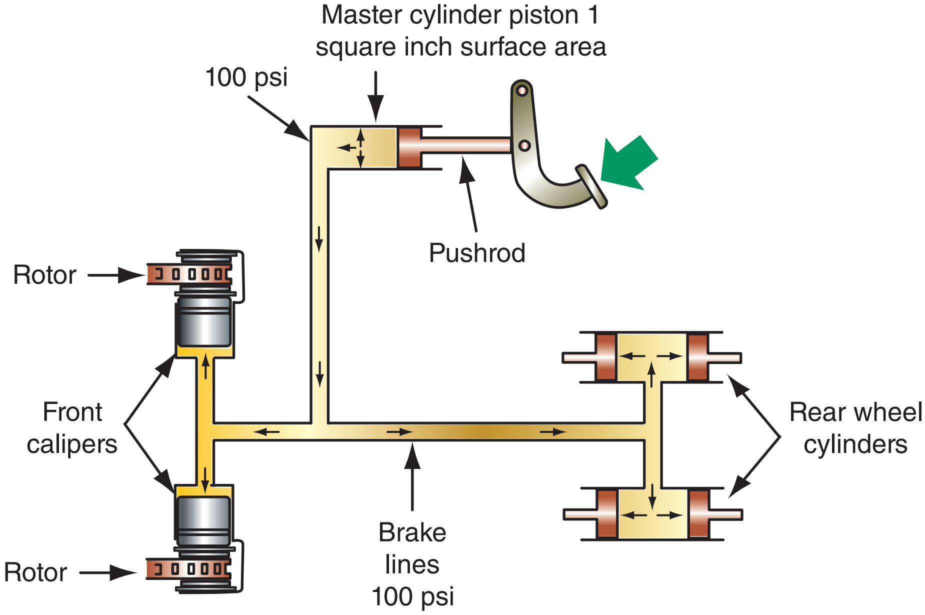

FIGURE 50–4 A schematic of a basic automotive hydraulic brake system.

pressure applied to a liquid in a closed system is transmitted by that liquid equally to every other part of that system. Apply a force of 100 pounds per square inch (psi) (690 kPa) through the master cylinder and you can measure 100 psi (690 kPa) anywhere in the lines and at each wheel where the brakes operate.

GO TO Chapter 3 for a discussion of Pascal's law.

The force can be increased at the output (i.e., at the wheel) by increasing the size of the piston, though piston travel decreases. The force at the output can be decreased by decreasing the size of the piston, but the piston travel increases **(Figure 50–5)**.

To increase the output force of the 100 psi (690 kPa) at the master cylinder to 500 psi (3,450 kPa) at the front wheels, simply use a caliper piston with a surface area of 5 square inches (32 sq. cm). To reduce the force of 100 psi (690 kPa), use a piston with 0.75 square inches (5 sq. cm) and 75 pounds (517 kPa) of output will result. No matter what the fluid pressure is, the output force can be increased with a larger piston, though piston travel decreases proportionately. In this example, 1 inch of travel of the master cylinder piston will result in $^1/_5$ of an inch movement by the caliper piston. In actual practice, fluid movement in an automotive hydraulic brake

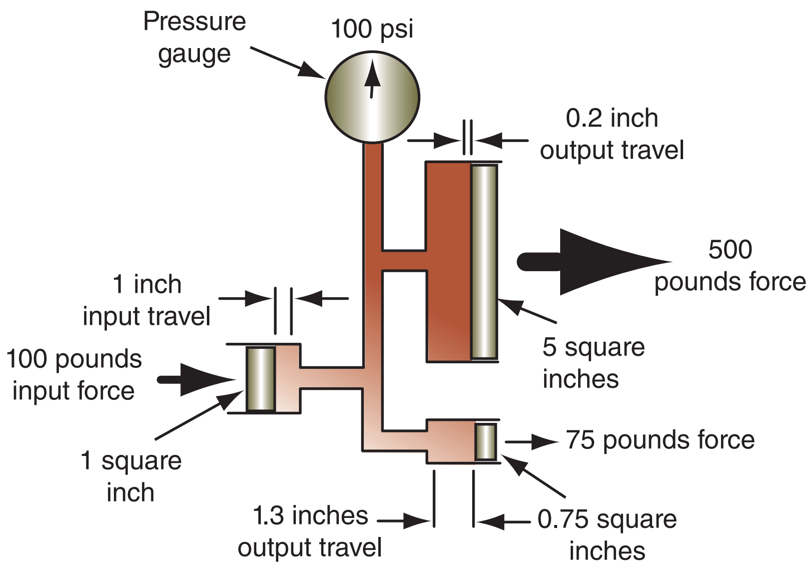

FIGURE 50–5 Output force increases with piston size.

system is very slight. In an emergency, when the pedal goes all the way to the floor, the volume of fluid displaced amounts to only about 20 cubic centimeters. About 15 cubic centimeters goes to the front discs and 5 cubic centimeters goes to the rear drums. Even under these conditions, the wheel cylinder and caliper pistons move only slightly.

Of course, the hydraulic system does not stop the car all by itself. In fact, it really just transmits the action of the driver's foot on the brake pedal out to the wheels. In the wheels, sets of friction pads are forced against rotors or drums to slow their turning and bring the car to a stop. Mechanical force (the driver stepping on the brake pedal) is changed into hydraulic pressure, which is changed back into mechanical force (brake shoes and disc pads contacting the drums and rotors).

The amount of force acting on the friction pads and shoes is determined by the input pressure and output piston sizes. The input pressure is based on $P = F/A$ or pressure is equal to force divided by the area. An input force of 100 pounds acting on a piston with 1 square inch of surface area creates 100 psi. If the piston size is reduced, say to 0.8 inches, pressure increases to 125 psi. Increasing input piston size decreases pressure as the force is applied over a larger area. Output force is equivalent to the pressure applied to the output piston multiplied by the area of the piston or $F = P{\cdot}A$. One hundred psi of pressure in the brake line applied to a caliper piston with 5 square inches of surface area will result in the caliper piston moving with 500 pounds of force.

Dual Braking Systems

Since 1967, federal law has required that all cars be equipped with two separate brake systems. If one circuit fails, the other provides enough braking power to safely stop the car.

The dual system differs from the single system by employing a tandem master cylinder, which is essentially two master cylinders formed by installing two separate pistons and fluid reservoirs into one cylinder bore. Each piston applies hydraulic pressure to two wheels **(Figure 50–6)**.

Front/Rear Split System In early dual systems, the hydraulic circuits were separated front and rear. Both front wheels were on one hydraulic circuit and both rear wheels on another. If a failure occurred in one system, the other system was still available to stop the vehicle. However, the front brakes do approximately 70 percent of the braking work. A failure in the front brake system would only leave 20 percent to 40 percent braking power. This problem was somewhat reduced with the development of diagonally split systems.

Diagonally Split System The diagonally split system operates on the same principles as the front and rear split system.

The hydraulic brake lines on this system, however, have been diagonally split front to rear (left front to right rear and right front to left rear). The circuit split can occur within the master cylinder or

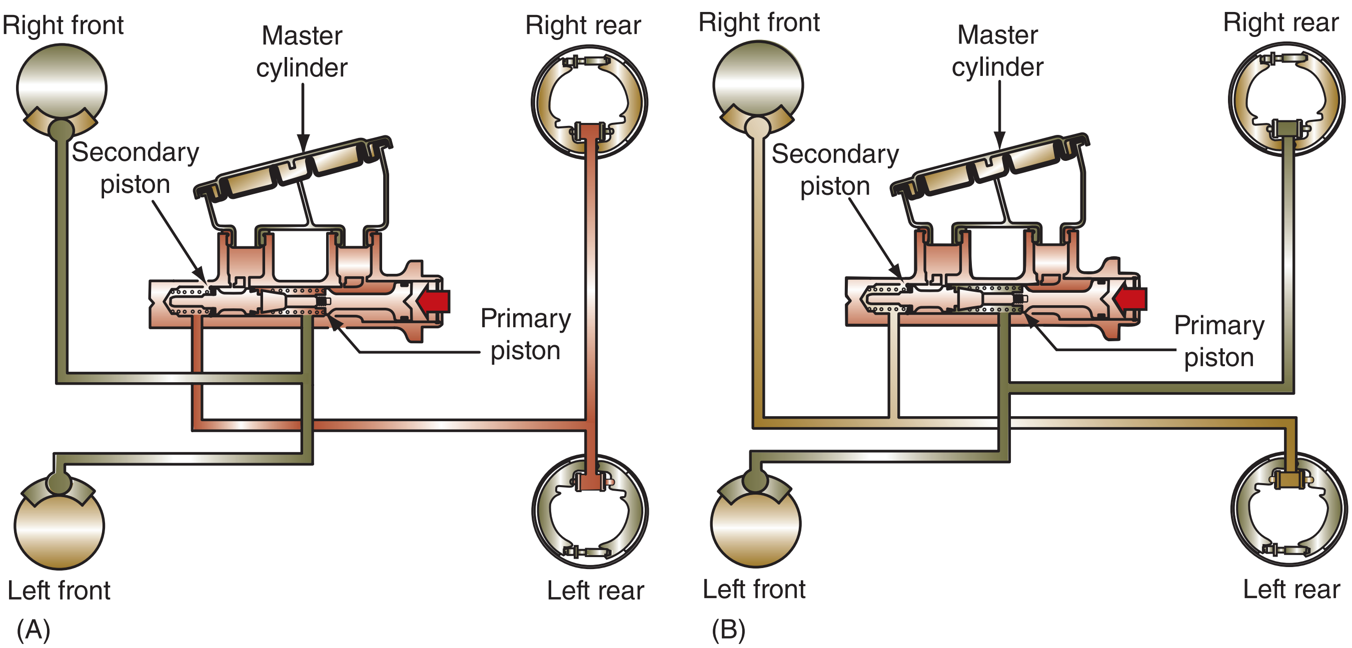

FIGURE 50–6 (A) A front/rear split of the braking system. (B) A diagonal split. The master cylinder is also split to allow pressure only to its designated wheel units.

externally at a proportioning valve or pressure differential switch.

In the event of a system failure, the remaining good system would do all the braking on one front wheel and the opposite rear wheel, thus maintaining 50 percent of the total braking force.

Hydraulic Brake System Components

The following sections describe the major components of a hydraulic brake system, including power-assisted systems and antilock braking systems.

Brake Fluid

Brake fluid is the lifeblood of any hydraulic brake system. It is what makes the system operate properly. Brake fluid is specially blended to perform a variety of functions. Brake fluid must be able to flow freely at extremely high temperatures (500 °F [260 °C]) and at very low temperatures (–104 °F [–75 °C]). Brake fluid also serves as a lubricant for many parts to ensure smooth and even operation. In addition, brake fluid must fight corrosion and rust in the brake lines and various assemblies and components. Another important property of brake fluid is that it must resist evaporation.

Most brake fluids are hygroscopic; that is, they readily absorb water. Moisture can enter the fluid when the fluid is exposed to the atmosphere and while it is in the brake system. For this reason, brake fluid should always be kept in a sealed container and should only be exposed to outside air for limited periods. Moisture also builds up in the fluid due to condensation. The fluid gets hot because of brake applications, and then when at rest it cools. This change in temperature causes condensation. Today's vehicles are more prone to hot brake fluid because there is little airflow under the hood to cool the fluid and braking system.

The performance of brake fluid is affected by moisture. As the amount of water in the fluid increases, the boiling point of the fluid decreases **(Figure 50–7)**. This can cause vapor to build in the system, which could lead to sudden brake failure or an unpredictable spongy pedal. Vapor is a gas and therefore is compressible. When pressure is applied to the brake fluid, it will compress the vapor before moving on through the system if it is able to do so.

The viscosity of the fluid at low temperatures is also affected by the amount of moisture. The viscosity increase, which means the fluid will have a harder time moving through the system, when it is cold. This means poor cold weather braking.

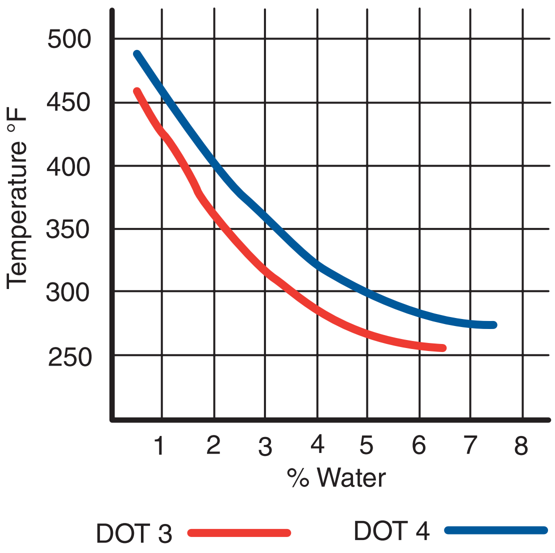

FIGURE 50–7 Moisture affects the boiling point of brake fluid.

Moisture may cause corrosion to build on internal parts of the system. This also decreases the efficiency of the brake system.

Tests have shown that within 1 year of service in a typical vehicle, the water content of the fluid is about 2 percent. It takes approximately 2 years for the fluid to have moisture levels that lower the fluid's boiling point to a dangerous level.

Brake fluid must be compatible with the materials used within the brake system to avoid damage to them. It must provide a controlled amount of swell to the brake system cups and seals. There must be just enough swell to form a good seal. However, the swell cannot be too great. If it is, brake drag and poor brake response occur.

Every can of brake fluid carries the identification letters of SAE and DOT. These letters (and corresponding numbers) indicate the nature, blend, and performance characteristics of that particular brand of brake fluid. Always use the fluid recommended by the manufacturer. The most commonly used brake fluids are DOT 3 and DOT 4. DOT 3 has a minimum dry boiling point of 401 °F (205 °C) and a minimum wet boiling point of 284 °F (140 °C). DOT 4 has a dry boiling point of 446 °F (230 °C) and a wet boiling point of 311 °F (155 °C). Dry boiling point means that the fluid has not absorbed any moisture and wet boiling point is when the fluid has absorbed 3 percent water by volume. Both DOT 3 and 4 are used as factory fill brake fluids and are clear to amber color when new.

DOT 5 is a silicone-based fluid and is purple in color and is not compatible with antilock brake systems or with DOT 3 or DOT 4 fluids. Some newer

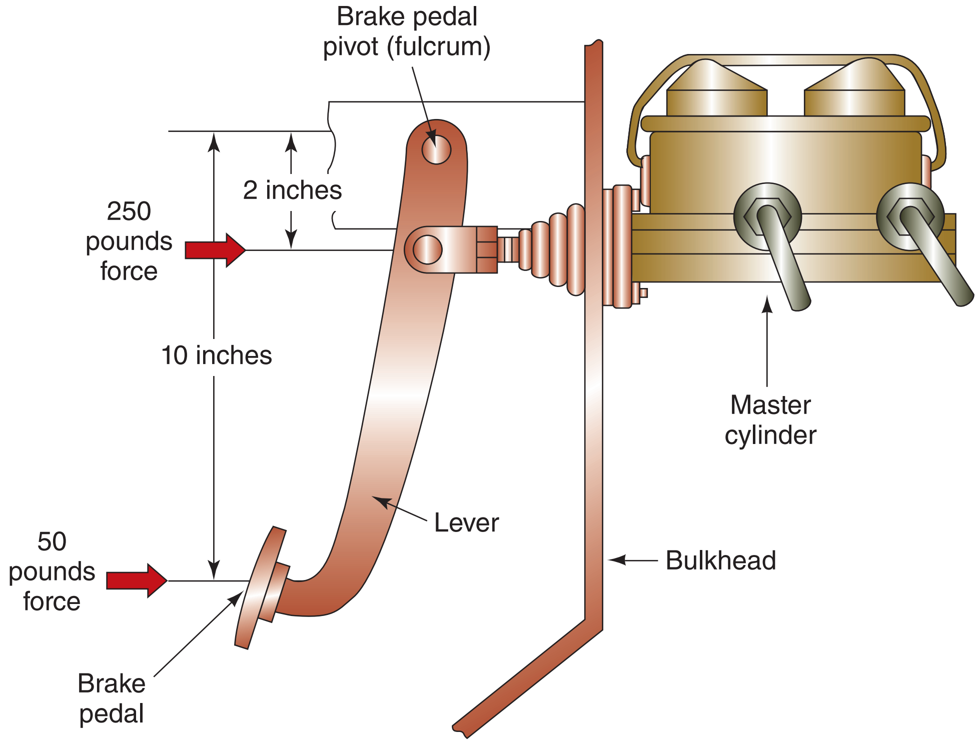

FIGURE 50–8 The brake pedal uses leverage to increase the force applied to the master cylinder.

vehicles specify DOT 5.1, which has a similar chemical make up to DOT 3 and 4. DOT 5.1 has a dry boiling point of 500 °F (260 °C) and a wet boiling point of 356 °F (180 °C).

GO TO Chapter 8 for details on the types of brake fluids.

GO TO Go to Chapter 53 for more information on ABS operation.

Warning! Use only approved brake fluid in a brake system. Any other lubricant that has a petroleum base must never be used. Petroleum-based fluids attack the rubber components in the brake system and cause them to swell and disintegrate.

Most vehicles have brake fluid level sensors that provide the driver with an early warning message when the brake fluid in the master cylinder reservoir has dropped below the normal level.

As the brake fluid in the master cylinder reservoir drops below the designated level, the sensor closes the warning message circuit. This illuminates the red BRAKE light or a LOW BRAKE FLUID lamp on the instrument panel. At this time, the fluid level should be checked.

Brake Pedal

The brake pedal is where the brake's hydraulic system gets its start. When the brake pedal is depressed, force is applied to the master cylinder. On a basic hydraulic brake system (where there is no power assist), the force applied is transmitted mechanically. As the pedal pivots, the force applied to it is multiplied mechanically. The force that the pushrod applies to the master cylinder piston is, therefore, much greater than the force applied to the brake pedal **(Figure 50–8)**.

Master Cylinders

The master cylinder **(Figure 50–9)** transmits the pressure on the brake pedal to each of the four wheel brakes to stop the vehicle. It changes the driver's mechanical pressure on the pedal to hydraulic

FIGURE 50-9 A brake master cylinder.

force, which is changed back to mechanical force at the wheel brake units. The master cylinder uses the fact that fluids are not compressible to transmit the pedal movement to the wheel brake units.

The master cylinder also uses hydraulics to increase the pedal force applied by the driver. A 100-pound force on the brake pedal can be used to push on a 1 sq. in. master cylinder piston to create a 100 psi pressure in the hydraulic system. This 100 psi can be used to push on 4 sq. in. output pistons at a wheel brake. The result is a 400-pound force at the 4 sq. in. output pistons. The driver's 100-pound force has been multiplied to a force of 400 pounds.

Dual-Piston Master Cylinders

Figure 50–10 is a simplified illustration of a dual master cylinder. A pushrod is connected to a piston inside the cylinder, and hydraulic fluid is in front of the piston. When the pedal is pressed, the piston is pushed forward. The fluid transmits the force of the piston to all the inner surfaces of the system. Only the pistons in the drum brake wheel cylinders and/or disc brake calipers can move, and they move outward to force the brake shoes or pads against the rotating brake drums and/or rotors.

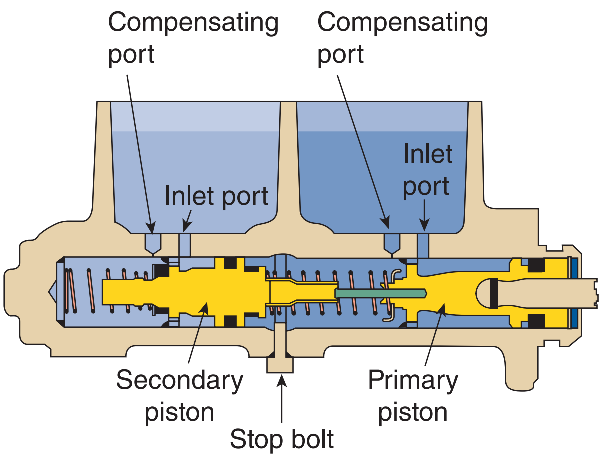

FIGURE 50-10 The basic components of a dual master cylinder.

Master Cylinder Reservoir The reservoir may be cast as one piece with the cylinder body, or it may be a separate molded nylon or plastic container **(Figure 50–11)**. The one-piece body and reservoir casting is usually made of cast iron, and are mostly found on older vehicles. The cylinder is directly below the reservoir. All reservoirs have a removable cover so that brake fluid can be added to the system. One-piece reservoirs typically have a single cover that is held on the reservoir with a retainer bail. Nylon or plastic reservoirs typically have two screw caps on top of the reservoir. Separate reservoirs may be clamped or bolted to the cylinder body, or they may be pressed into holes at the top of the body and sealed with grommets or O-rings.

The caps or covers are vented to prevent a vacuum lock as the fluid level drops in the reservoir. A flexible rubber diaphragm at the top of the reservoir is incorporated in the caps or covers. The diaphragm separates the brake fluid from the air above it while remaining free to move up and down with changes in fluid level. The diaphragm keeps the moisture and air from entering the brake fluid in the reservoir.

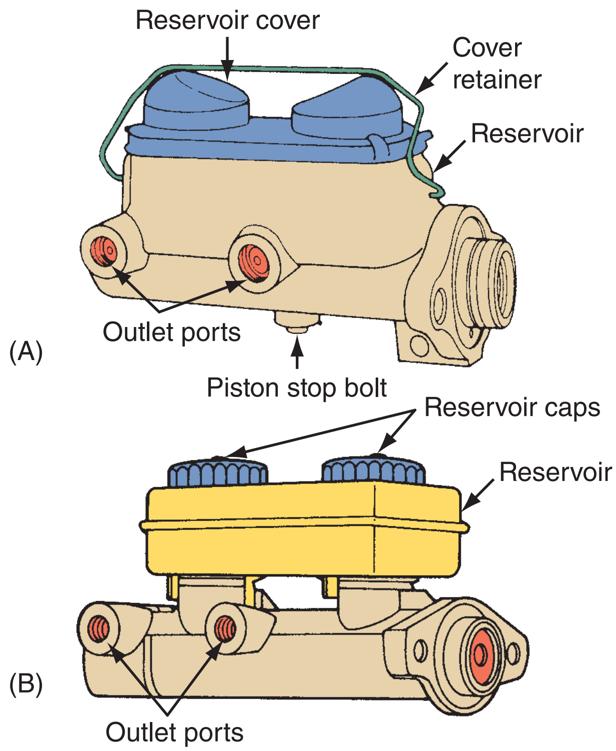

FIGURE 50-11 (A) A typical cast-iron dual master cylinder and (B) a typical aluminum/composite dual master cylinder.

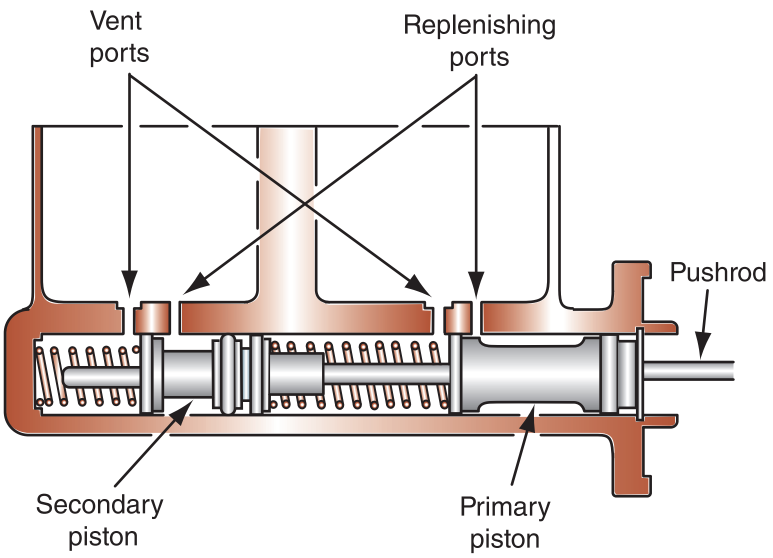

FIGURE 50–12 Fluid from the reservoir fills the cylinder through the replenishing ports.

If a vehicle with front disc and rear drum brakes has a hydraulic system split front to rear, the reservoir chamber for the disc brakes is larger than the chamber for the drum brakes. As disc pads wear, the caliper pistons move out farther in their bores. More fluid is then required to keep the system full in the master cylinder. With drum brake wheel cylinder pistons, the volume of fluid does not increase much with lining wear because the pistons always fully retract into the cylinders regardless of brake lining wear. Vehicles with four-wheel disc brakes or diagonally split hydraulic systems usually have master cylinders with equally sized reservoirs because each circuit of the hydraulic system requires the same volume of fluid.

Plastic reservoirs are often translucent so that fluid level can be seen without removing the cover. Although this feature allows a quick check of fluid level without opening the system to the air, you should not rely on it for thorough brake fluid inspection. Stains inside the reservoir can give a false indication of fluid level, and contamination cannot be seen without removing the reservoir caps or cover.

Master Cylinder Ports Different names have been used for the ports in the master cylinder. This text refers to the forward port as the "vent" port and the rearward port as the "replenishing" port. These are the names established by SAE Standard J1153. The **vent port** has been called a compensating port or a replenishing port. To further confuse the issue, the **replenishing port** has been described by many manufacturers as the compensating port, as well as the vent port, the by-pass port or hole, the filler port, or the intake port **(Figure 50–12)**. The vent ports and replenishing ports let fluid pass between each pressure chamber and its fluid reservoir during operation. The names of these ports are not important as long as you understand their purposes and operations.

Master Cylinder Construction

A single cylinder bore contains two piston assemblies **(Figure 50–13)**. The piston assembly at the rear is the primary piston, and the one at the front is the secondary piston. Each piston has a return spring in front of it. There is a **cup seal** in front of each piston and a cup or seal at the rear of each piston. The seals retain fluid in the cylinders and prevent seepage between the cylinders.

Inside the cylinder are two spool-shaped pistons. The piston has a head on one end and a groove for

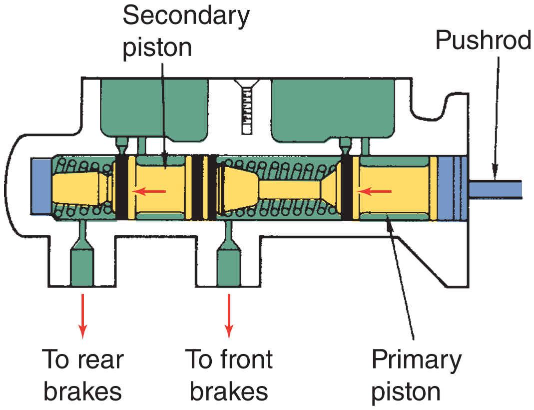

FIGURE 50–13 The position of the pistons in a master cylinder when the brakes are applied. Notice that the seals stop fluid flow throughout the master cylinder.

an O-ring seal on the other end. The seal seats against the cylinder wall and keeps fluid from leaking past the piston. The smaller diameter center of the piston is the valley or spool area, which lets fluid get behind the head of the piston.

Each master cylinder piston works with a rubber cup seal, which fits in front of the piston head. The cup has flexible lips that fit against the cylinder walls to seal fluid pressure ahead of the piston head. The cup lip also can bend to let fluid get around the cup from behind. When the brakes are applied, pressure in front of the cup forces the lip tightly against the cylinder wall, enabling it to hold very high pressure. The lip of a cup seal is always installed toward the pressure to be contained or away from the body of the piston. The cup seals in only one direction. If pressure behind the lip exceeds the pressure in front of it, the higher pressure will force the lip away from the cylinder wall and let fluid bypass the cup.

Pistons have small coil springs that return the pistons to the proper position when the brake pedal is released. Sometimes the springs are attached to the pistons; sometimes they are separate parts. A snapring holds the components inside the cylinder, and a rubber boot fits around the rear of the cylinder and pushrod to keep dirt from entering the cylinder **(Figure 50–14)**.

A two-piece master cylinder has an aluminum body. Because aluminum can be nicked or gouged easily, the bore of the aluminum cylinder is anodized to protect it from wear and damage. They are fitted with a removable nylon or plastic reservoir. Because

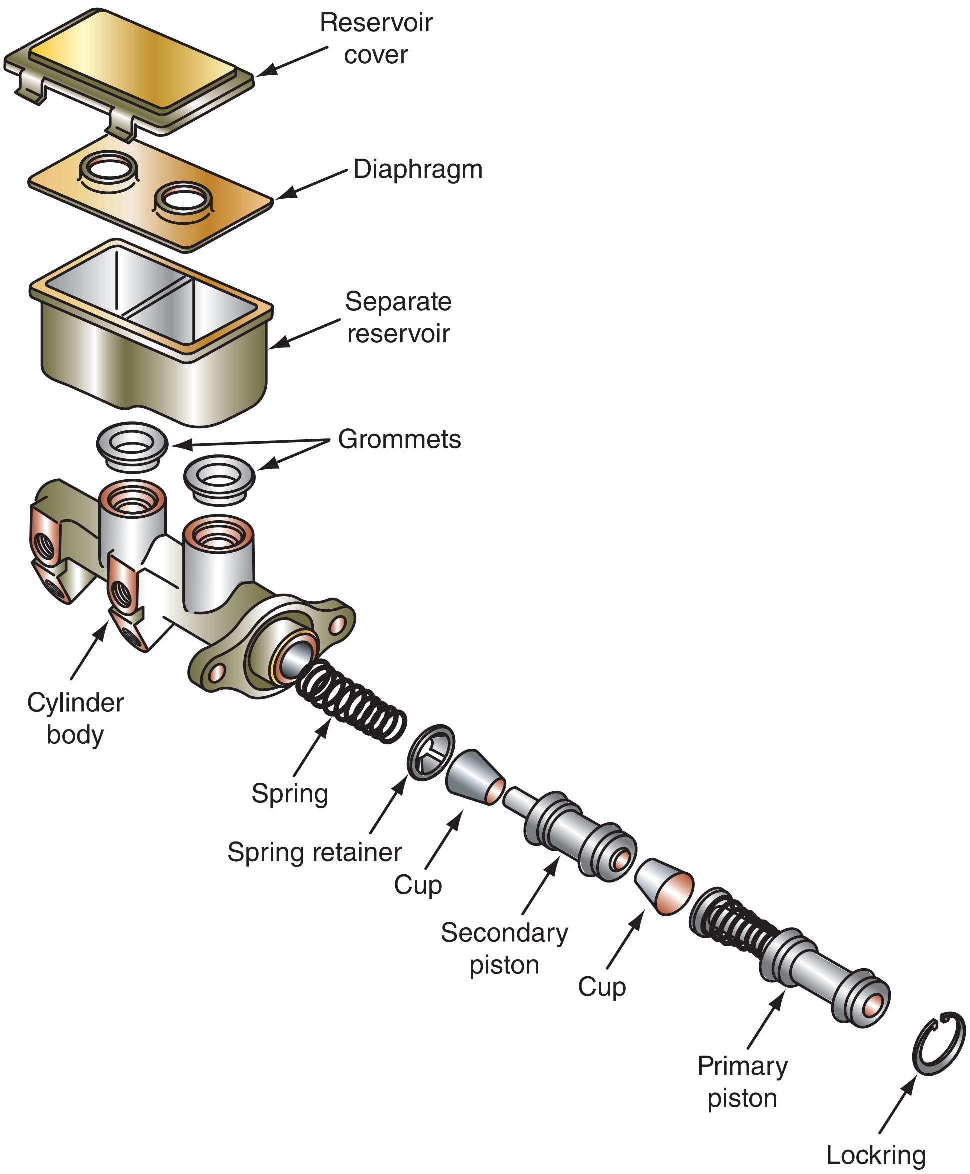

FIGURE 50–14 The basic construction of a dual master cylinder.

the master cylinder is made of two materials, it is often called a composite master cylinder. The pistons, cups, and springs used in a composite master cylinder are essentially the same and work the same way as those in a one-piece master cylinder.

Master Cylinder Operation

The vent port in the bottom of the reservoir is located just ahead of the piston cup. Fluid flows from the reservoir into the pressure chamber in front of the piston cup. The replenishing port is located above the valley area of the piston behind the piston head. The O-ring seal on the piston keeps the fluid from leaking out the rear of the cylinder. The return spring in front of the piston and cup returns the piston when the brakes are released.

When the driver depresses the brake pedal, the pushrod pushes the piston forward. As it moves forward, the piston pushes the cup past the vent port. As soon as the vent port is covered, fluid is trapped ahead of the cup. The fluid, which is under pressure, goes through the outlet lines to the wheel brake units to apply the brakes.

When the driver releases the brake pedal, the return spring forces the piston back to its released position. As the piston moves back, it pulls away from the fluid faster than the fluid can flow back from the brake lines to the pressure chamber. This creates a low pressure ahead of the piston.

The piston must rapidly move back to the released position so it can be ready for another forward stroke if necessary. The low-pressure area must be filled with fluid as the piston moves back. A path for fluid flow is provided by the valley area, past the primary cup protector washer and through several small holes in the head of the piston, or by having enough clearance between the piston head and the cylinder bore. Fluid flows through the piston or around the lip of the cup and into the chamber ahead of the piston. This flow quickly relieves the low-pressure condition.

The fluid that flows from the valley area to the pressure chamber must be replaced. When the piston is fully returned to its released position, the space in front of it is full of fluid. The piston cup again seals off the head of the piston. In the meantime, the fluid from the rest of the system has begun to flow back to the high-pressure chamber. If this pressure is not released, the brakes would not release. The returning fluid flows back to the reservoir through the vent port. The vent port is covered by the piston cup at all times, except when the piston is released.

Residual Pressure Check Valve

The pressure chamber in a master cylinder for some drum brake systems may have an additional part called a residual pressure check valve. This valve can be installed in the pressure chamber or the outlet line of the master cylinder. A residual pressure check valve is the oldest type of pressure control valve used in a brake system.

When you replace a master cylinder, it is very important to verify whether or not the vehicle requires a residual pressure check valve. Installing the wrong cylinder will cause improper brake operation and possible system failure.

Split Hydraulic Systems

Most late-model vehicles have a diagonally split hydraulic system. If there is a hydraulic failure in the brake lines served by the master cylinder's secondary piston, both pistons will move forward when the brakes are applied, but there is nothing to resist piston travel except the secondary piston spring. This lets the primary piston buildup only a small amount of pressure until the secondary piston bottoms in the cylinder bore. Then the primary piston will build enough hydraulic pressure to operate the brakes served by this half of the system.

In case of a hydraulic failure in the brake system served by the primary piston, the piston will move forward when the brakes are applied but will not buildup hydraulic pressure. Very little force is transferred to the secondary piston through the primary piston spring until the piston extension screw comes in contact with the secondary piston. Then, pushrod force is transmitted directly to the secondary piston and enough pressure is built up to operate its brakes.

Fast-Fill and Quick Take-Up Master Cylinders

Several manufacturers use fast-fill, or quick take-up, master cylinders. These cylinders fill the hydraulic system quickly to take up the slack in the caliper pistons of low-drag disc brakes. Low-drag calipers retract the pistons and pads farther from the rotor

than traditional calipers. This reduces friction and brake drag and improves fuel mileage.

If a conventional master cylinder were used with low-drag calipers, excessive pedal travel would be needed on the first stroke to fill the lines and calipers with fluid and take up the slack in the pads. To overcome this, fast-fill, or **quick take-up**, master cylinders provide a large volume of fluid on the first stroke of the brake pedal.

You can recognize a fast-fill, or quick take-up, master cylinder by the bulge, or larger diameter, on the outside of the casting **(Figure 50–15)**. The cylinder has a larger diameter bore for the rear primary piston than the front primary piston. Inside the cylinder, a fast-fill, or quick take-up, valve replaces the conventional vent and replenishing ports for the primary piston. Some master cylinders for four-wheel disc brakes also have a quick take-up valve for the secondary piston.

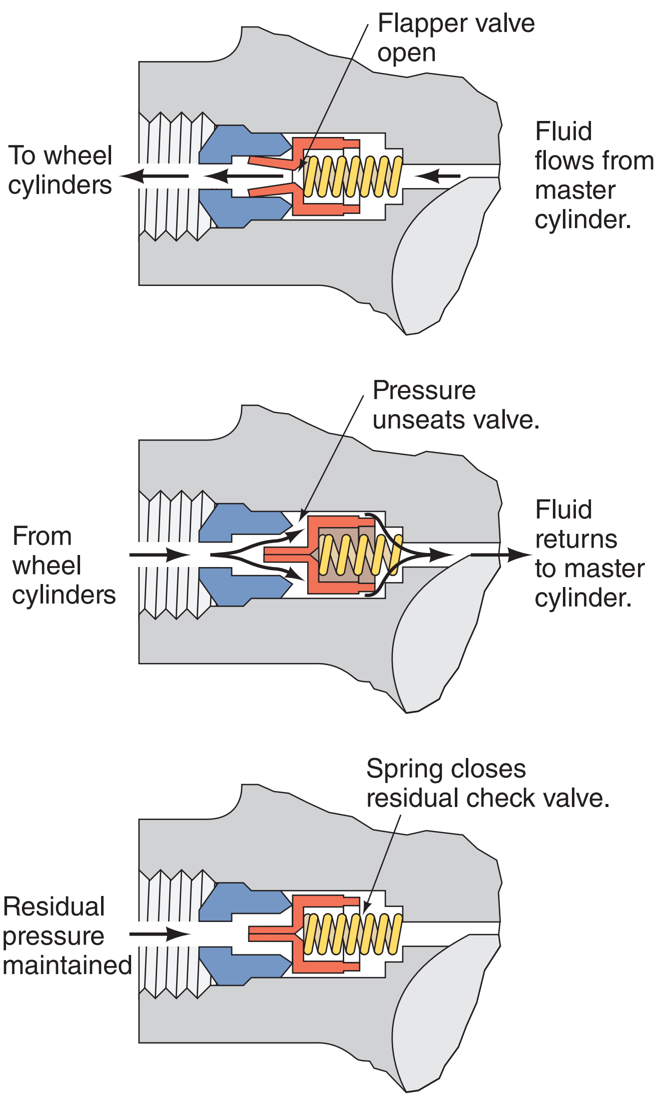

FIGURE 50–15 The operation of a master cylinder's residual valve.

The quick take-up valve contains a spring-loaded check ball that has a small by-pass groove cut in the edge of its seat. The outer circumference of the valve is sealed to the cylinder body with a lip seal. Several holes around the edge of the hole let fluid bypass the lip seal under certain conditions. Some valves (those more often called "fast-fill" valves) are pressed into the cylinder body and sealed tightly by an O-ring. A rubber flapper-type check valve under the fast-fill valve performs the same functions as a lip seal of a quick take-up valve.

Brakes Not Applied When the brakes are off, both master cylinder pistons are retracted, and all vent and replenishing ports are open. However, fluid to both ports of the primary piston must flow through the groove in the check ball seat.

Brakes Applied As the brakes are applied, the primary piston moves forward in its bore. Remember that the diameter of the primary chamber is larger than the diameter of the secondary. As the secondary piston moves forward, the volume is reduced. This causes hydraulic pressure to instantly rise in the low-pressure chamber. The higher pressure forces the large volume of fluid into the low-pressure chamber past the cup seal of the primary piston. This provides the extra volume of fluid to take up the slack in the caliper pistons.

The lip seal of the quick take-up valve keeps fluid from flowing from the low-pressure chamber back to the reservoir. Initially a small amount of fluid bypasses the check ball through the by-pass groove, but this is not enough to affect quick take-up operation.

As brake application continues, pressure in the low-pressure chamber rises to about 70 to 100 psi. The check ball in the quick take-up valve then opens to let excess fluid return to the reservoir. Pressures in both chambers of the primary piston equalize, and the piston moves forward to actuate the secondary piston.

All of the actions apply to the primary piston if it is serving front disc brakes and the secondary piston is serving drum brakes. If the hydraulic system is diagonally split, or if the car has four-wheel, low-drag discs, the quick take-up fluid volume must be available to both pistons. Some master cylinders have a second quick take-up valve for the secondary piston. Others provide the needed fluid volume through the design of the cylinder itself. As long as the primary quick take-up valve stays closed, the fluid bypassing the primary piston cup causes the secondary piston to move farther. This provides equal fluid displacement from both pistons and maintains equal pressure in the system. When the

quick take-up valve opens, both pistons move together just as in any other master cylinder.

Brakes Released When the driver releases the brake pedal, the return springs force the primary and secondary pistons to move back. Pressure drops in the high-pressure chambers, and fluid bypasses the piston cup seals from the low-pressure chambers. Low pressure is created in the low-pressure chamber, which allows atmospheric pressure to move past the lip seal of the quick take-up valve. Fluid from the reservoir then flows through both the vent and replenishing ports to equalize pressure in the pressure chambers and valley areas.

On the return stroke, fluid flows to the secondary piston through the replenishing port unless the secondary piston also has a quick take-up valve. If a secondary quick take-up valve is installed, it works in the same way as a primary quick take-up valve.

Central-Valve Master Cylinders

Some antilock brake systems (ABS) use master cylinders that have central check valves in the tops of the pistons **(Figure 50–16)**. These valves are designed to prevent seal damage and pedal vibration. If the master cylinder provides pressure during antilock operation and the system also has a motor-driven pump, the master cylinder's pistons may shift back and forth rapidly during antilock operation. This will cause excessive pedal vibration and—more importantly—wear on the piston cups where they pass over the vent ports.

FIGURE 50–16 You can recognize a quick take-up master cylinder by the bulge or step in the casting.

When the brakes are released, fluid flows from the replenishing ports to the low-pressure chambers, through the open central check valves, and into the high-pressure chambers. As the brakes are applied, the central valves close to hold fluid in the high-pressure chambers. When the brakes are released again, the check valves open to let fluid flow back through the pistons to the low-pressure chambers and the reservoir.

The central check valves provide supplementary fluid passages to let fluid move rapidly back and forth between the high- and low-pressure chambers during antilock operation. This is not much different in principle from non-ABS fluid flow, but the extra passages reduce piston and pedal vibration and cup seal wear.

Hydraulic Tubes and Hoses

Fluid transfer from the driver-actuated master cylinder is routed through one or more valves and then into the steel tubing and hoses **(Figure 50–17)**. The design of the brake lines offers quick fluid transfer response with very little friction loss. Engineering and installing the brake lines so they do not wrap around sharp curves is very important in maintaining this good fluid transfer.

Brake Line Tubing

Most brake line tubing consists of copper-fused double-wall steel tubing in diameters ranging from $^{1}/_{8}$ to $^{3}/_{8}$ inch (3 mm to 9 mm). Some OEM brake tubing is manufactured with soft steel strips, sheathed with copper. The strips are rolled into a double-wall assembly and then bonded in a furnace at extremely high temperatures. Corrosion protection is often added by tin-plating the tubing.

Fittings

Assorted fittings are used to connect steel tubing to junction blocks or other tubing sections. The most common fitting on older vehicles is the double or inverted flare style. Double flaring is important to maintain the strength and safety of the system. Single flare or sleeve compression fittings may not hold up in the rigorous operating environment of a standard vehicle brake system.

Fittings are constructed of steel or brass and use either the inverted flare or standard flare fitting **(Figure 50–18)**. The two types of flares are not

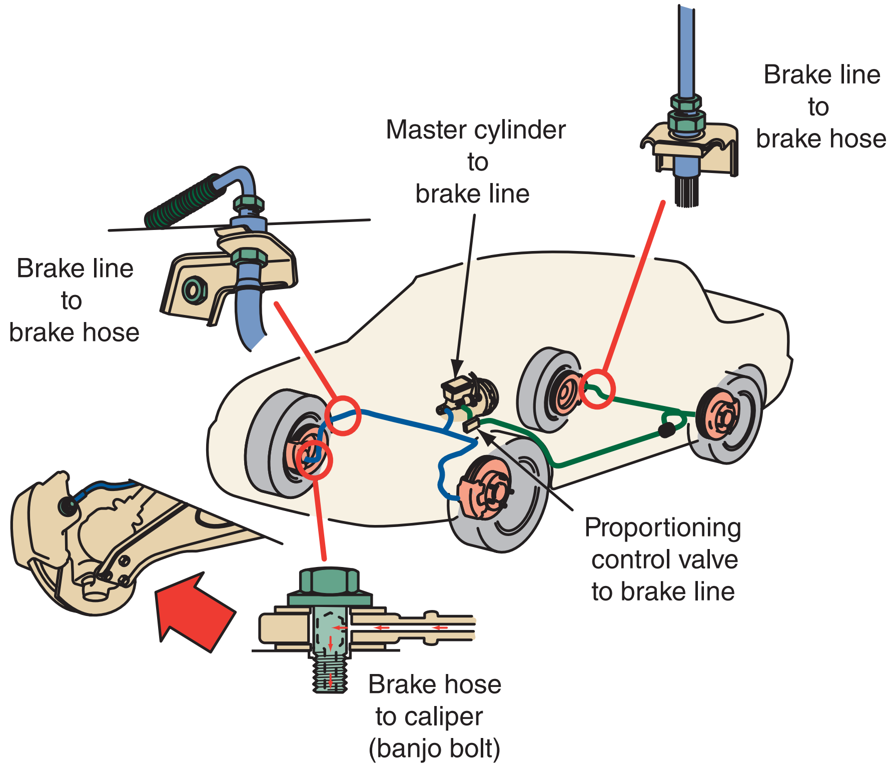

FIGURE 50-17 A typical layout of the hoses and tubes for the brake system.

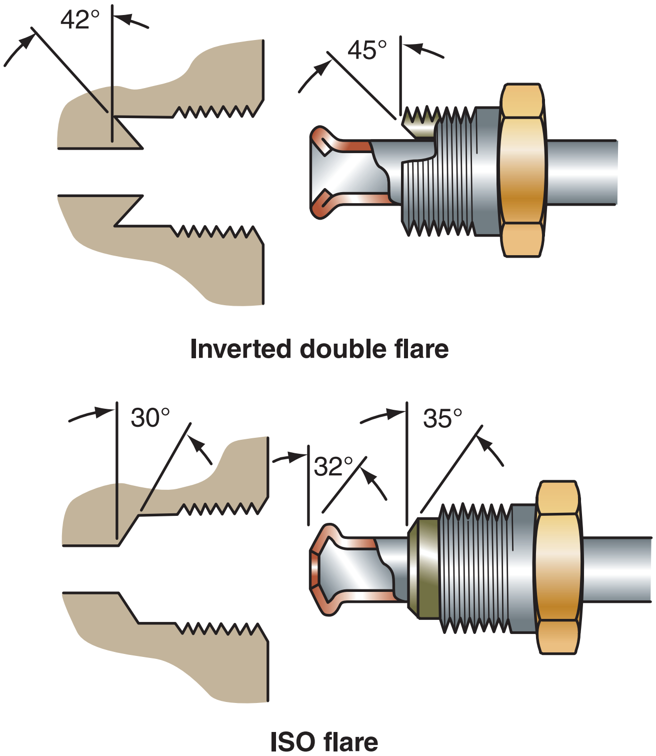

FIGURE 50-18 The two types of flares, double and ISO or bubble, are not interchangeable.

SHOP TALK

Never use copper tubing as a replacement for defective lines or hoses. This type of tubing is subject to fatigue, cracking, and corrosion. If a section of the brake tubing is damaged, the entire section must be installed with a new tube of the same type, size, shape, and length. Also, when installing tubing, hoses, or connectors, tighten all connections to specifications. This is especially important with the hollow bolts that connect brake hoses to the calipers. Overtightening these bolts, even a little, can cause them to snap. When installing a new hose, position the hose to avoid contact with other vehicle components. After installation, bleed the brake system.

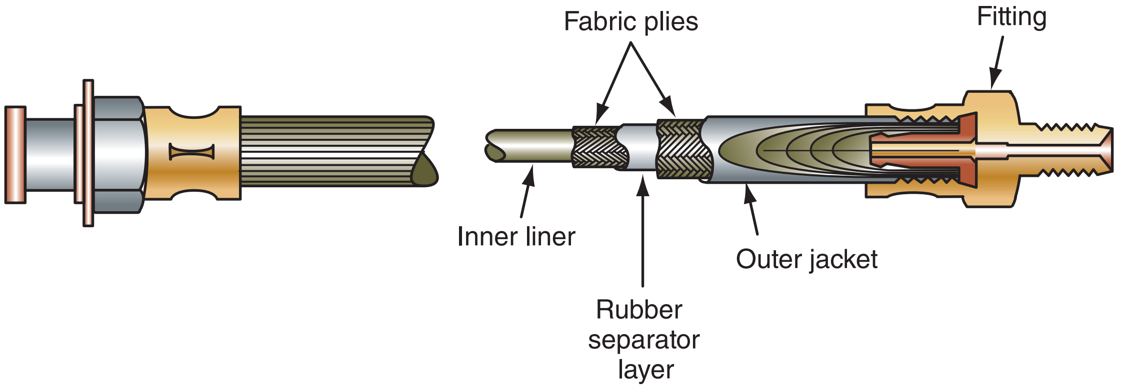

FIGURE 50–19 Flexible brake hoses are constructed of layers of reinforcement materials.

interchangeable and will not seal threaded together. Newer vehicles may use the ISO or metric bubble flare fitting though ISO fittings are now the most common.

Never change the style of fitting being used on the vehicle. Replace ISO fittings only with ISO fittings. Replace standard fittings with standard fittings.

The metal composition of the fittings must also match exactly. Using an aluminum-alloy fitting with steel tubing may provide a good initial seal, but the dissimilar metals create a corrosion cell that eats away the metal and reduces the connection's service life.

Brake Line Hoses

Brake line hoses offer flexible connections to wheel units so steering and suspension members can operate without damaging the brake system. Typical brake hoses range from 10 to 30 inches (25 to 76 mm) in length and are constructed of multiple layers of fabric impregnated with a synthetic rubber **(Figure 50–19)**. Brake hose material must offer high heat resistance and withstand harsh operating conditions.

SHOP TALK

Many brake hose failures can be traced to errors made during the replacement or repair of the hose. Twisted hoses become stressed and are prime candidates for leaks and bursting. Most manufacturers now print a natural lay indicator or line on the hose. By making sure this line is not spiralled after fittings are tightened, you can ensure the hose is not overly stressed. Also, always use a hose of the same length and diameter as the original during servicing to maintain brake balance at all wheels.

Hydraulic System Safety Switches and Valves

Switches and valves are installed in the brake system hydraulic lines to act as warning devices and as pressure control devices. Though the adoption of four-wheel disc brakes and antilock brake systems has decreased the use of most valves in the hydraulic system, some vehicles still use one or more valves for pressure control or to illuminate the brake warning light. Late-model vehicles with ABS and stability control use the ABS to control pressures to the wheel brakes and no external valves are used.

Pressure Differential Valve

A pressure differential valve, in the event of a hydraulic leak, is used to shut off one hydraulic circuit and operate a warning light switch. Its main purpose is to tell the driver if pressure is lost in either of the two hydraulic systems. Since each brake hydraulic system functions independently, it is possible the driver might not notice immediately that pressure and braking are lost. When a pressure loss occurs, brake pedal travel increases and pedal feel typically becomes soft, spongy, and much less firm. This

results in a more-than-usual effort to slow and stop the vehicle. Should the driver not notice the difference, the warning light is actuated by the hydraulic system safety switch.

Under normal conditions, the hydraulic pressure on each side of the pressure differential valve piston is balanced. The piston is located at its center point, so the spring-loaded warning switch plunger fits into the tapered groove of the piston. This leaves the contacts of the warning switch open. The brake warning light stays off.

If there is a leak in the front or rear braking system, the hydraulic pressure in the two systems is unequal. For example, if there is a leak in the system supplying the front brakes, there is lower pressure in the front system when the brake pedal is applied. The hydraulic pressure in the rear system then pushes the piston toward the front side, where the pressure is lower. As the piston moves, the plunger is pushed out **(Figure 50–20)**. This closes the switch and illuminates the brake warning light.

While all brake warning light switches serve the same function, there are three common variations in the design of these switches. These variations include switch with centering springs, without centering springs, and with centering springs and two pistons.

Metering and Proportioning Valves

Metering and proportioning valves are used to balance the braking characteristics of disc and drum brakes.

The braking response of the disc brakes is immediate when the brake pedal is applied. It is directly proportionate to the effort applied at the pedal. Drum brake response is delayed while rear brake hydraulic pressure moves the wheel cylinder pistons to overcome the force of their return springs and

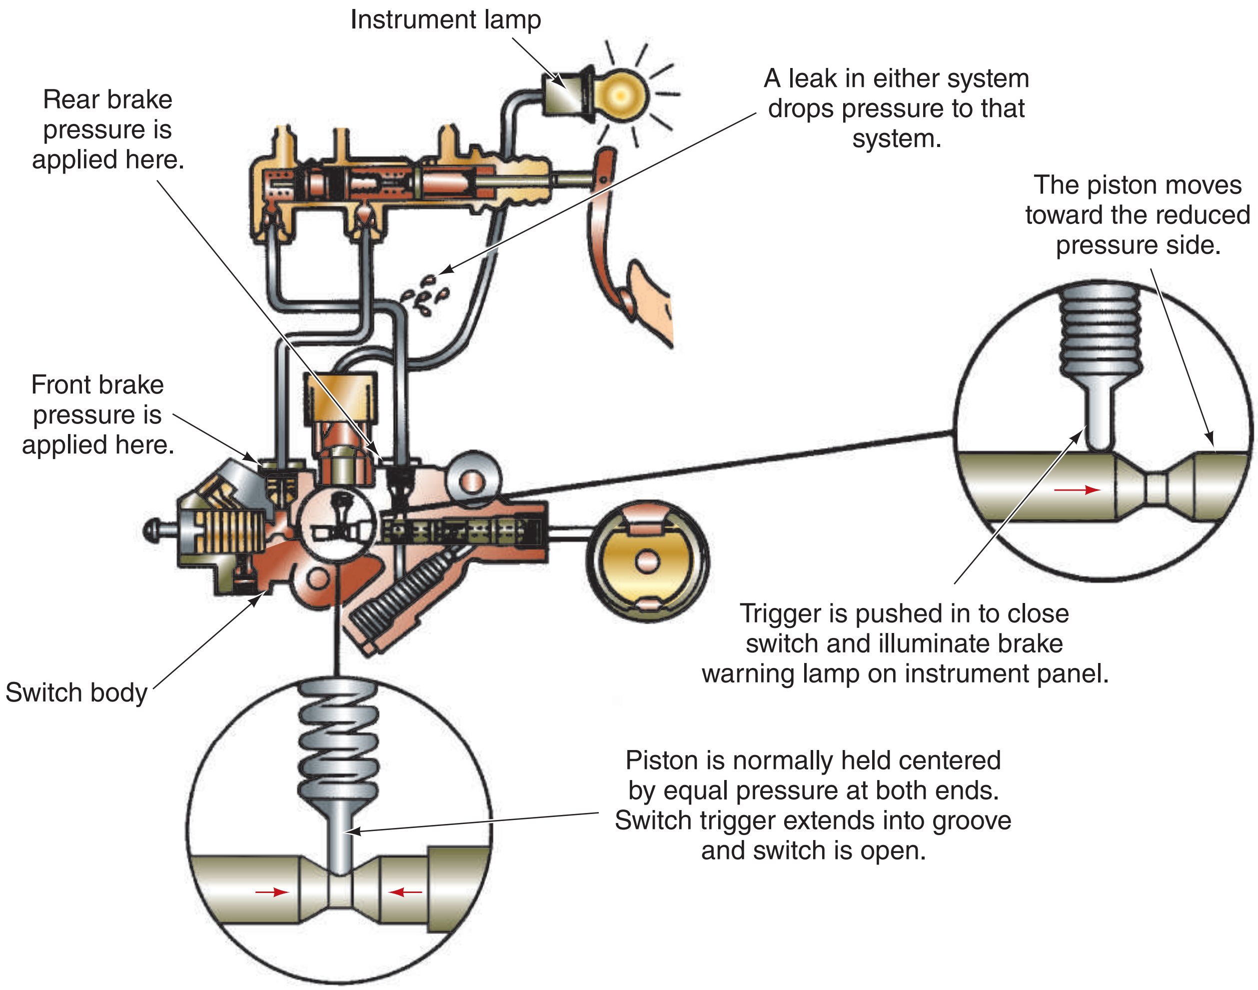

FIGURE 50–20 The action of a pressure differential valve when there is a leak in the system.

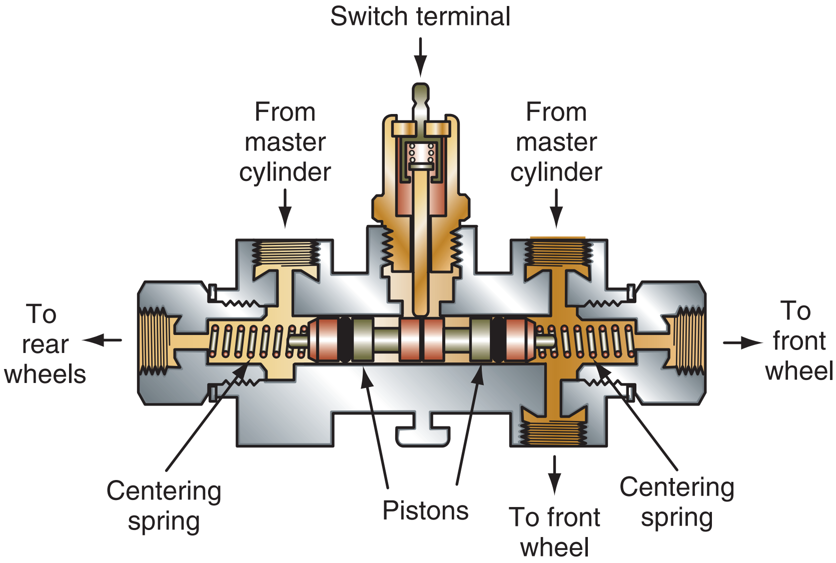

FIGURE 50–21 The pressure differential valve can turn on the brake warning light if a drop in pressure occurs in the hydraulic system.

force the brake shoes to contact the drum. Once applied, their actions may be self-energizing and tend to multiply the pedal effort. This reduces the need for increasing pressure to the rear brakes.

Metering Valve A **metering valve** (hold-off valve) in the front brake line holds off pressure going from the master cylinder to the front disc calipers. This delay allows pressure to buildup in the rear drums first. When the rear brakes begin to take hold, the hydraulic pressure builds to the level needed to open the metering valve **(Figure 50–21)**. When the metering valve opens, line pressure is high enough to operate the front discs. This process provides for better balance of the front and rear brakes. It also prevents lockup of the front brakes by keeping pressure from them until the rear brakes have started to operate. The metering valve has the most effect at the start of each brake operation and all during light braking conditions.

Proportioning Valve The self-energizing action of the delayed response rear drum brakes can cause them to lock the rear wheels at a lower hydraulic pressure than the front brakes. The **proportioning valve** (balance valve) **(Figure 50–22)** is used to control rear brake pressures, particularly during hard stops. When the pressure to the rear brakes reaches a specified level, the proportioning valve overcomes the force of its spring-loaded piston, stopping the flow of fluid to the rear brakes. By doing so, it regulates rear brake system pressure and adjusts for the difference in

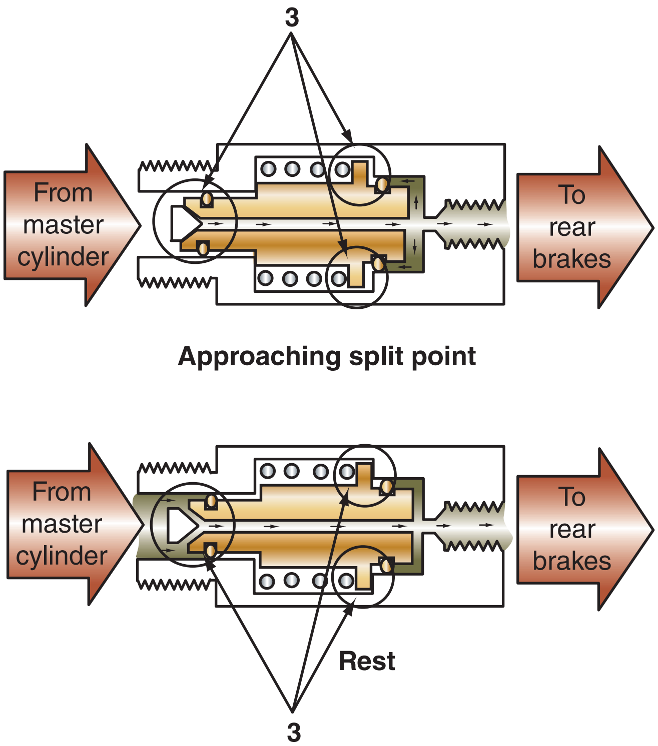

FIGURE 50–22 A proportioning valve.

pressure between front and rear brake systems. This keeps front and rear braking forces in balance.

Height-Sensing Proportional Valve The height-sensing proportional valve provides two different brake balance modes to the rear brakes based on

vehicle load. This is accomplished by turning the valve on or off. When the vehicle is not loaded, hydraulic pressure is reduced to the rear brakes. When the vehicle is carrying a full load, the actuator lever moves up to change the valve's setting. The valve now allows full hydraulic pressure to the rear brakes. The valve contains a plunger, cam, torsional clutch spring, and an actuator shaft **(Figure 50–23)**.

The valve is mounted to the frame above the rear axle and has an actuator lever connected by a link to the lower shock absorber bracket. The valve is turned on and off as the axle-to-frame height changes due to load in the vehicle. The torsional clutch spring attached to the valve shaft is used as an override. Once the valve is positioned during braking, the spring prevents the valve from changing position if the vehicle goes over a bump or moves off the road.

Height-sensing proportional valves are replaced when defective and are not adjustable.

Combination Valves Most older cars and trucks have a **combination valve (Figure 50–24)** in their hydraulic system. This valve is simply a single unit that combines the metering and proportioning valves with the pressure differential valve. Combination valves are described as three-function or two-function valves, depending on the number of functions they perform in the hydraulic system.

Three-Function Valve. This type of valve performs the functions of the metering valve, brake warning light switch, and proportioning valve.

Two-Function Valves. There are two variations of the two-function combination valve. One variation works the proportioning valve and brake warning light switch functions. The other performs the metering valve and brake warning light switch functions.

If any one of its several operations fail, the entire combination valve must be replaced, because these units are not repairable.

Warning Lights

A wide variety of electrical and electronic components are found in a brake system, especially with ABS. These include the warning lamp switch operation of a pressure differential valve and the electrical switches to operate the parking brake warning light, hydraulic failure warning lamp, as well as sensors to indicate low brake fluid level **(Figure 50–25)**.

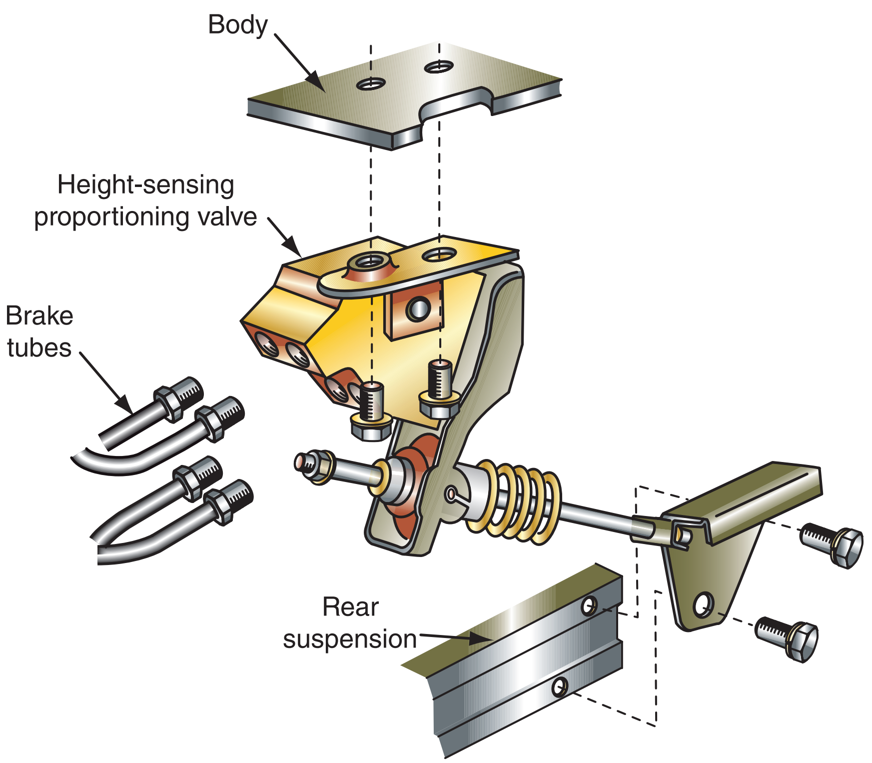

FIGURE 50–23 A height-sensing proportional valve.

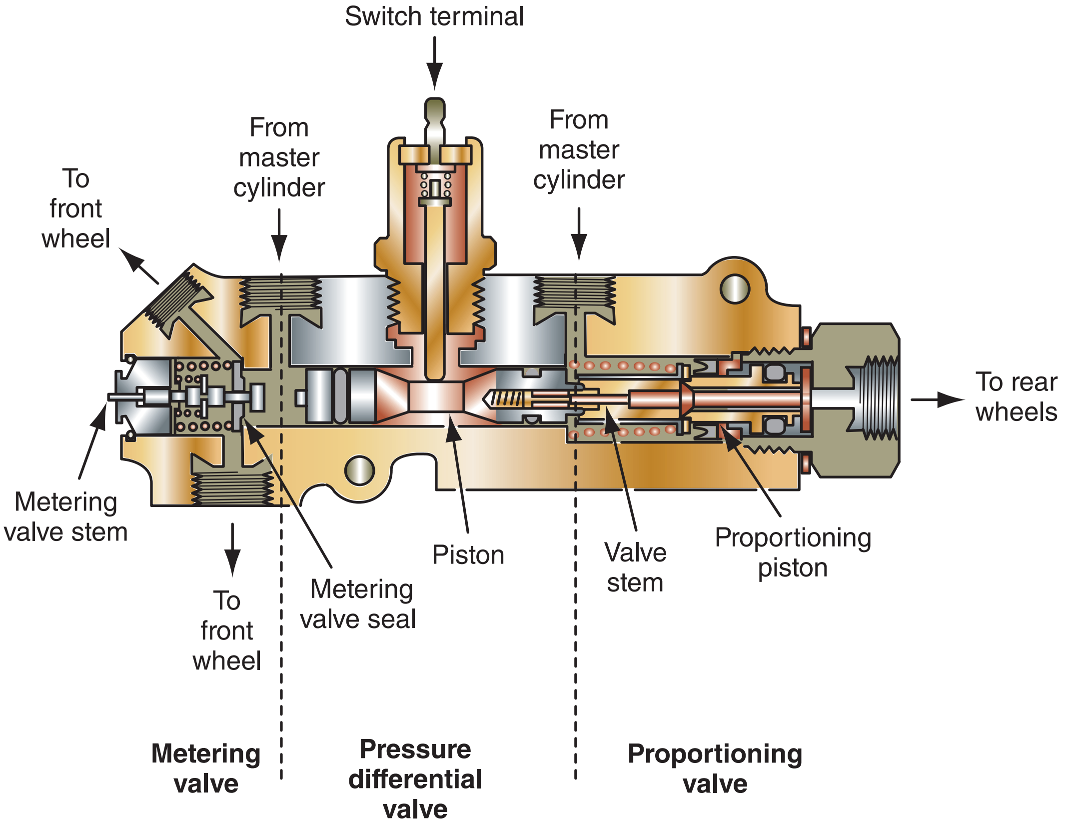

FIGURE 50–24 A typical combination valve.

Failure Warning Lamp Switch The pressure differential valve has a hydraulically operated switch that controls the brake failure warning lamp on the instrument panel. Each side of the pressure differential valve is connected to half of the hydraulic system (one chamber of the master cylinder). Each master cylinder piston provides pressure to a separate hydraulic system. If one of the circuits fails, the brake pedal travel will increase and more brake pedal effort will be required to stop the car. The driver might not notice a problem, however, but the lamp on the instrument panel will provide a warning in case of hydraulic failure.

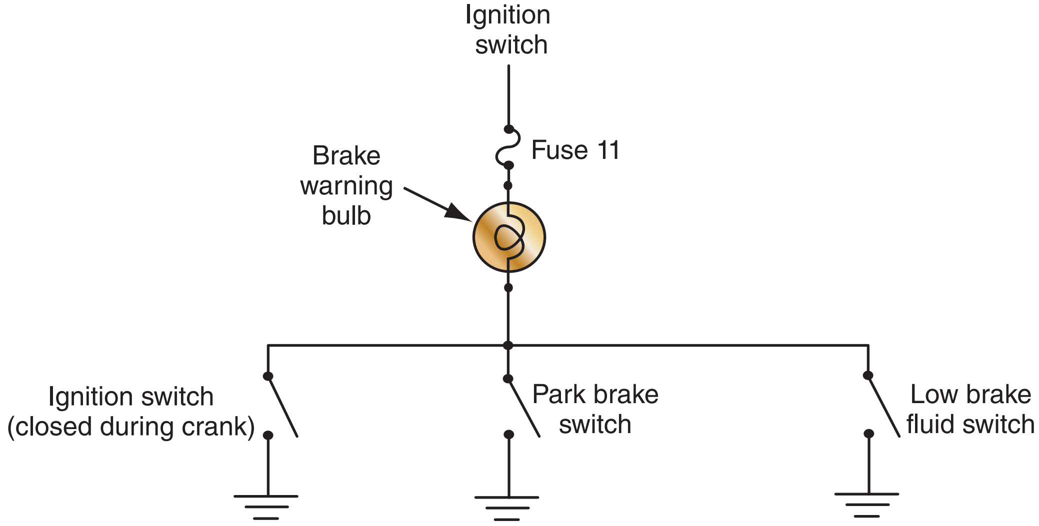

FIGURE 50–25 An example of a brake warning light circuit.

Failure in one half of the hydraulic system causes a pressure loss on one side of the pressure differential valve. Pressure on the other side moves the valve's plunger into contact with the switch terminal. This closes the circuit and the warning lamp is illuminated. All pressure differential valves work in this basic way but differ in the details of the shape of the piston and the use of centering springs.

The pressure differential valve on most late-model vehicles is part of a combination valve or built into the body of the master cylinder. Some vehicles have a switch in the float assembly of the fluid reservoir instead of a pressure differential valve. This float switch turns on the brake warning lamp when the fluid level changes to a dangerous point. This accomplishes the same thing as a pressure differential valve.

Master Cylinder Fluid Level Switch Because brake fluid level is important to safe braking, many vehicles have a fluid level switch that causes illumination of the instrument panel's red brake warning lamp when the fluid level is too low. This warning system is similar to the pressure differential valve because fluid level in the reservoir will drop from a leak caused by hydraulic failure. Therefore, a fluid level switch has replaced the pressure differential valve on many vehicles **(Figure 50–26)**. An added advantage of a fluid level switch is that it will alert the driver of a dangerous fluid level caused by inattention and poor maintenance practices.

Fluid level sensors are built into the reservoir body or cap. One type has a float with a pair of switch contacts on a rod that extends above the float. If the fluid level drops too low, the float will drop and cause the rod-mounted contacts to touch

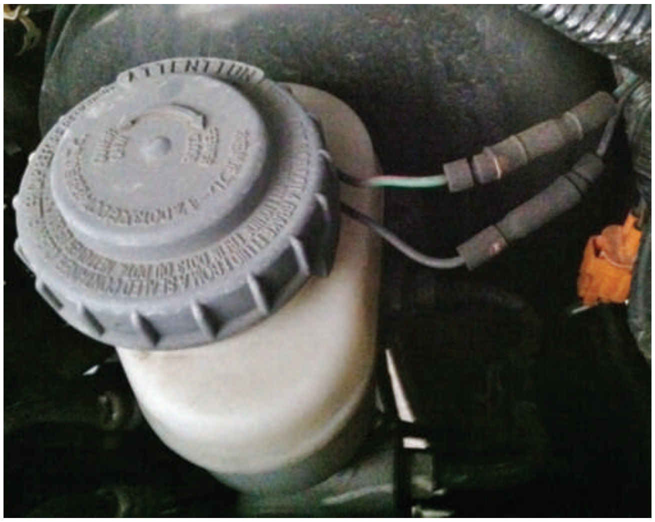

FIGURE 50–26 A reservoir cap with a fluid level sensor built in.

a set of fixed contacts and close the lamp circuit. Another type of switch uses a magnet in a movable float. If the float drops low enough, the magnet pulls a set of switch contacts together to close the lamp circuit. The contacts typically provide a ground path for the brake warning lamp.

Parking Brake Switch The parking brake should only be applied to hold a vehicle stationary. If the parking brake is even partially applied while the vehicle is moving, it will produce enough heat to glaze friction materials, expand drum dimensions, and increase pedal travel. On rear disc brake systems with integral parking brake actuators, driving with the parking brake applied will distort the brake rotors and reduce pad life.

A normally closed, single-pole, single-throw switch is used to ground the circuit of the red brake warning lamp in the instrument cluster. This switch is located within the parking brake handle or pedal assembly and is designed to turn on the light whenever the parking brake is applied.

Some vehicles with daytime running lights (DRL) use the parking brake switch to complete a circuit that prevents the headlights from coming on if the parking brake is applied when the engine is started. When the parking brake is released, the DRLs operate normally.

Stop Lamps

Stop lamps are included in the right and left tail lamp assemblies. Vehicles built since 1986 also have a center high-mounted stop lamp (CHMSL).

Brake stop lamp switches are operated hydraulically or mechanically. Hydraulic switches were used on older vehicles and were installed in the master cylinder's high-pressure chamber; they were activated by system pressure. A mechanical switch is mounted on the bracket for the brake pedal and activated by the movement of the pedal lever **(Figure 50–27)**.

Mechanical switches are found on some vehicles because they can be adjusted to illuminate the stop lamps with the slightest pedal movement. Stop lamp switches may be single-function or multifunction units. Single-function switches have only one set of switch contacts that control electric current to the stop lamps at the rear of the vehicle. Multifunction switches have one set of switch contacts for the stop lamps and at least one additional set of contacts for the CHMSL, cruise control, or ABS. Some multifunction switches have contacts for all of these functions.

Modern vehicles use brake pedal position sensors. The output from the sensor is used by the ABS,

FIGURE 50–27 An example of a brake pedal position sensor.

traction/stability control, lighting, transmission, engine, and other modules. BPP sensors often are used to monitor pedal position, force applied to the pedal, and the speed with which it is being applied so the ABS and stability control systems can correctly apply the wheel brakes based on operating conditions.

Drum and Disc Brake Assemblies

Although drum and disc brakes are explained in great detail in later chapters, a brief explanation of their components and operating principles is essential at this point.

Drum Brakes

A drum brake assembly consists of a cast-iron drum, which is bolted to and rotates with the vehicle's wheel, and a fixed backing plate to which the shoes, wheel cylinders, automatic adjusters, and linkages are attached **(Figure 50–28)**. Additionally, there might be

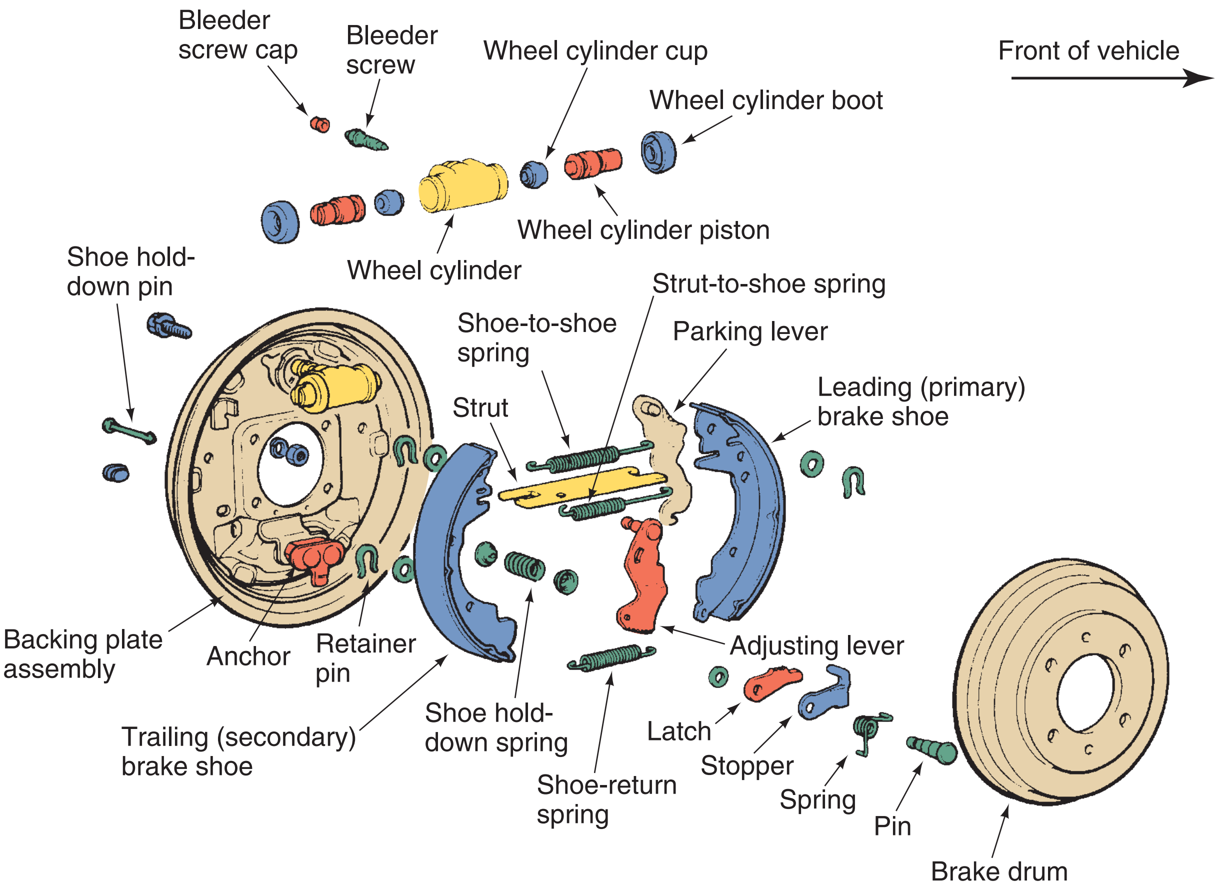

FIGURE 50–28 Typical nonservo drum brake assembly.

some extra hardware for parking brakes. The shoes are surfaced with frictional linings, which contact the inside of the drum when the brakes are applied. The shoes are forced outward by pistons located inside the wheel cylinder. The pistons are actuated by hydraulic pressure. As the drum rubs against the shoes, the energy of the moving drum is transformed into heat. This heat energy is passed into the atmosphere. When the brake pedal is released, hydraulic pressure drops and the pistons are pulled back to their unapplied position by return springs.

Disc Brakes

Disc brakes resemble the brakes on a bicycle: the friction elements are in the form of pads, which are squeezed or clamped about the edge of a rotating wheel. With automotive disc brakes, this wheel is a separate unit, called a **rotor**, inboard of the vehicle wheel **(Figure 50–29)**. The rotor is typically made of cast iron. Since the pads clamp against both sides of it, both sides are machined smooth. Usually the two surfaces are separated by a finned center section for better cooling (such rotors are called **ventilated rotors**). The pads are attached to a metal backing and held in place inside the body of the caliper. As with the drum brakes, the pads are actuated by pistons and hydraulic pressure. The pistons are contained within a caliper assembly, a housing that wraps around the edge of the rotor. The caliper is kept from rotating by way of bolts holding it to the car's suspension framework.

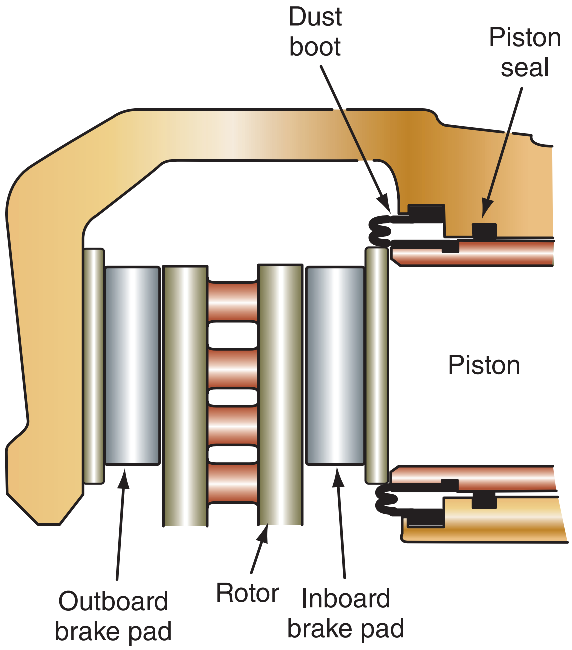

FIGURE 50–29 A view of how the disc brake caliper, pads, and rotor are arranged.

The **caliper** is a housing containing the pistons and related seals, springs, and boots as well as the cylinders and fluid passages necessary to force the friction linings or pads against the rotor. The caliper resembles a hand in the way it wraps around the edge of the rotor. It is attached to the steering knuckle. Some models use spring pressure to keep the pads close against the rotor. In other caliper designs this is achieved by a square-cut seal that distorts during brake application and returns to its original position as the brakes are released. This assists in retracting the piston into its cylinder and moves the pad off the rotor.

Unlike shoes in a drum brake, the pads act perpendicular to the rotation of the disc when the brakes are applied. This effect is different from that produced in a brake drum, where frictional drag actually pulls the shoe into the drum. Disc brakes are said to be non–self-energizing and so require more force to achieve the same braking effort. For this reason, they are ordinarily used in conjunction with a power brake unit.

Hydraulic System Service

Hydraulic system service is relatively uncomplicated, but it is vital to the vehicle's safe operation.

Warning! To check brake fluid level, you should observe the fluid through the reservoir and not remove the cap unless necessary. This helps prevent moisture from getting to the fluid. If the master cylinder cover must be removed, clean the cover before removal to avoid dropping dirt into the reservoir.

Brake Fluid Inspection

There are many ways to check for contaminated fluid. The color of the fluid is not always a good indication of its condition. Most brake fluids should be clear to amber in color but will darken with age. If the fluid is cloudy or thick, it is contaminated. The fluid can also be checked by placing a small amount of fluid in a clear glass jar. If the fluid is dirty or separates into layers, it is contaminated.

FIGURE 50-30 A test strip can be used to check for copper contaminants in the brake fluid.

Test strips are also available. A strip of treated paper is dipped into the reservoir **(Figure 50–30)**. The paper will change colors corresponding to the condition of the fluid. The resulting color is then matched to the color chart that accompanies the test strips.

Special brake fluid testers are also available. These measure the fluid's boiling point, which is an indication of moisture content **(Figure 50–31)**.

FIGURE 50-31 Using a moisture tester to check brake fluid condition.

Contaminated brake fluid can damage rubber parts and cause leaks. To rid the system of contaminated brake fluid, the system should be flushed and refilled with new fluid.

If the brake fluid level is low and there are no signs of external leaks, it is likely the brake pads are nearing their wear limit. As the disc brake pad linings and rotors wear, the caliper pistons extend further out of the caliper bore. This increases the volume of fluid inside the calipers and reduces the fluid level in the master cylinder reservoir. If the fluid level is low, possibly causing the brake warning light to illuminate and no leaks are present, recommend to the customer to have the entire brake system inspected to check for worn linings.

Master Cylinder Inspection

Master cylinder problems are quite common but not always readily evident. However, there are times when the master cylinder is suspect and the problem lies elsewhere. Accurate and logical troubleshooting is the only way to truly determine if the master cylinder is working properly. Although brake pedal response and reservoir fluid levels are strong indicators of problems with the master cylinder or hydraulic system, other tests can be performed to help pinpoint the problem.

Check the master cylinder housing for cracks and damage **(Figure 50–32)**. Look for drops of brake

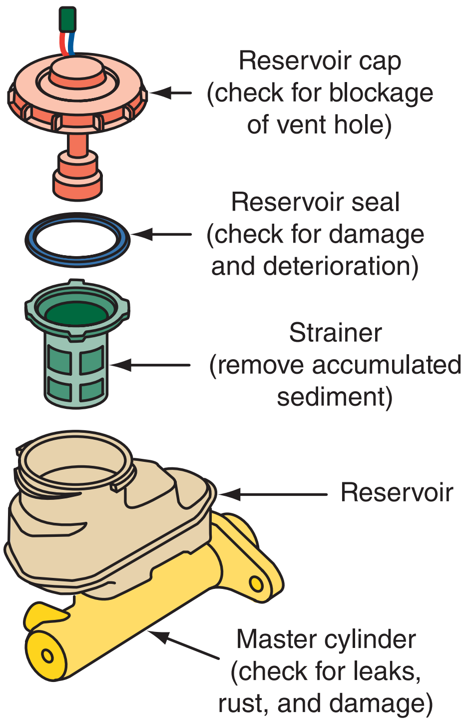

FIGURE 50-32 When inspecting a master cylinder, make sure to carefully check these items.

fluid around and behind the master cylinder. If a reservoir chamber is cracked, it may be completely empty and the surrounding area may be dry. This is because the fluid drained very quickly and has had time to evaporate or wash away. But with only one-half of the brake system operational, the brake warning lamp should be lit and a test drive should reveal the loss of braking power.

If the master cylinder has two separate fluid reservoirs, refill the master cylinder reservoir section that is empty and apply the brakes several times. Wait 5 to 10 minutes and check for leakage or fluid level drop in the reservoir.

Hydraulic brake system leaks can be internal or external. Most internal leaks are actually fluid bypassing the cups in the master cylinder. If the cups lose their ability to seal the pistons, brake fluid leaks past the cups and the pistons cannot develop system pressure **(Figure 50–33)**.

Internal and external rubber parts wear with use or can deteriorate with age or fluid contamination. Moisture or dirt in the hydraulic system can cause corrosion or deposits to form in the bore, resulting in the wear of the cylinder bore or its parts. Although internal leaks do not cause a loss of brake fluid, they can result in a loss of brake performance. Internal leakage will cause sinking pedal complaints and can be hard to pinpoint.

If the primary piston cup seal is leaking, the fluid will bypass the seal and move between the vent and replenishing ports for that reservoir or, in some cases, between reservoirs.

If there are no signs of external leakage, but the brake warning lamp is lit, the master cylinder may have an internal leak. To check for an internal leak in the master cylinder, remove the master cylinder cover and be sure the reservoirs are at least half full. Watch the fluid levels in the reservoirs while a helper slowly presses the brake pedal and then quickly releases it. If the fluid level rises slightly under steady pressure, the piston cups are probably leaking. Fluid level rising in one reservoir and falling in the other as the brake pedal is pressed and released also can indicate that fluid is bypassing the piston cups. Replace or rebuild the master cylinder if there is evidence of leakage.

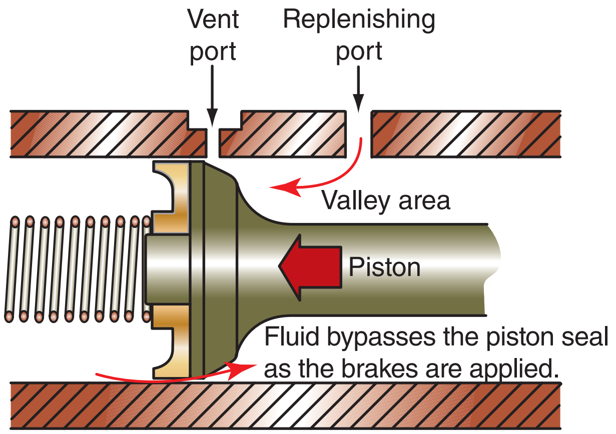

FIGURE 50–33 Fluid can leak or bypass around the piston seals in the master cylinder, causing a low pedal and poor braking.

Another quick test for internal leakage is to hold pressure on the brake pedal for about 1 minute. If the pedal drops but no sign of external leakage exists, fluid is probably bypassing the piston cups.

Quick Take-Up Valve Checks The quick take-up valve is used to provide a high volume of fluid on the first pedal stroke. This action takes up the slack in the low-drag caliper pistons. No direct test method exists for a quick take-up valve, but excessive pedal travel on the first stroke may indicate that fluid is bypassing the valve. If this symptom exists, check for a damaged or unseated valve. If the pedal returns slowly when the brakes are released, the quick take-up valve may be clogged so that fluid flow from the cylinder to the reservoir is delayed.

Air Entrapment Test

Poor pedal feel or action may be caused by trapped air in the system. Trapped air can be the result of a worn or defective master cylinder or other parts of the system. Air will also enter the system if there is a fluid leak. If there are no signs of leaks, check the system for trapped air.

To check for entrapped air, remove the cover of the master cylinder and make sure the reservoirs are filled to the proper level. Hold the cover and gasket against the reservoir top but do not secure it with its clamp or screws. Then have an assistant pump the brake pedal ten to twenty times rapidly and maintain pressure after the last pedal application. Remove the cover and have the assistant quickly release pedal pressure. Watch for a squirt of brake fluid from the reservoirs. If air is compressed in the system, it

> **Caution!** This test may result in brake fluid bubbling or spraying out of the master cylinder reservoir. Wear safety goggles. Cover the master cylinder reservoirs with clear plastic wrap or other suitable cover to keep brake fluid off the vehicle's paint.

will force fluid back through the compensating ports faster than normal and cause fluid to squirt in the reservoir. If a fluid squirt appears in one side of the reservoir but not the other, that side of the split hydraulic system contains the trapped air. If there is air trapped in the system, bleed the system and recheck.

System Flushing

Currently, more than a dozen manufacturers specify periodic brake fluid changes for some, or all, of their models built during the past 12 years. Change intervals vary from as often as every 12 months or 15,000 miles to as infrequently as every 60,000 miles. All brake systems accumulate sludge over some period of time. Flushing the system can remove this sludge and any moisture, but once you have disturbed the sludge, you want to be sure you get it *all* out of the system. Stirring up sludge from the master cylinder reservoir may cause it to get into ABS valves and pumps if you do not get it all out of the system.

Brake hoses for disc brakes usually enter the caliper near the top of the caliper body. The bleeder valve is also located at the top of the caliper bore. If sludge accumulates in the caliper bore, it collects at the bottom. A quick, superficial bleeding of the caliper will not flush out the sludge and all of the old fluid. To flush a caliper thoroughly, pump several ounces of fluid through it. On some vehicles during brake pad replacement, you may want to remove the caliper from its mounts and retract the piston to force out all the old fluid. Then reinstall it and thoroughly flush it with fresh fluid.

Flushing should be done at each bleeder screw in the same manner as bleeding. Open the bleeder screw approximately one and a half turns and force fluid through the system until the fluid emerges clear and uncontaminated. Do this at each bleeder screw in the system. After all lines have been flushed, bleed the system using one of the common bleeding procedures. All contaminated fluid should be drawn out of the master cylinder reservoir before bleeding. Make sure you dispose of the old brake fluid in the proper manner.

Brake Line Inspection Check all tubing, hoses, and connections from under the hood to the wheels for leaks and damage **(Figure 50–34)**. Rusted-through brake lines are common. Look closely where lines are held in place with clamps and brackets. Moisture and road salt can collect at these points and eat away at the lines. Check the flexible hoses for rotting, bulging, cracking, and damage from rubbing against other components. Also check for weak areas where the hose may balloon out under pressure. Many hoses have a white line along their length **(Figure 50–35)**. This line helps to show if the hose is twisted and kinked, a situation that can occur from improper disc brake service. Check parking brake linkage, cable, and connections for damage and wear. Replace parts where necessary.

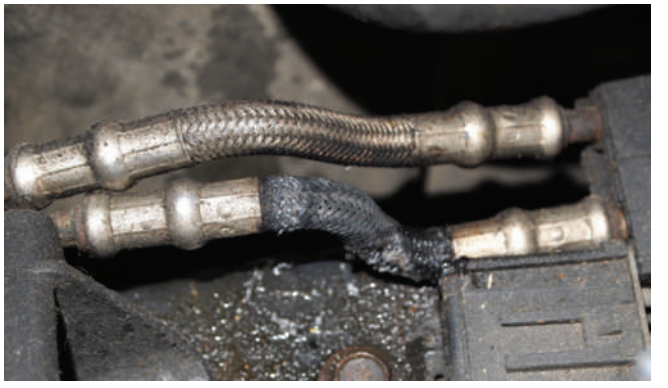

FIGURE 50-34 A leaking steel brake line.

Brake Pedal Inspection Depress and release the brake pedal several times (engine running for power brakes). Check for friction and noise. Pedal movement should be smooth, with no squeaks from the pedal or brakes. The pedal should return quickly when it is released.

When operating the engine, be sure the transmission lever is in neutral or park. Be sure the area is properly ventilated for the exhaust to escape.

FIGURE 50-35 The white line indicates the correct positioning of the hose.

Apply heavy foot pressure to the brake pedal (engine running for power brakes). Check for a spongy pedal and pedal reserve. Spongy pedal action is springy. Pedal action should feel firm. Pedal reserve is the distance between the brake pedal and the floor after the pedal has been depressed fully. The pedal should not go lower than 1 or 2 inches (25 or 50 mm) above the floor.

With the engine off, hold light foot pressure on the pedal for about 15 seconds. There should be no pedal movement during this time. Pedal movement indicates a leak. Repeat the procedure using heavy pedal pressure (engine running for power brakes).

If there is pedal movement but the fluid level is not low, the master cylinder has internal leakage. It must be rebuilt or replaced. If the fluid level is low, there may be an external leak somewhere in the brake system. The leak must be repaired.

Depress the pedal and check for proper stoplight operation.

To check power brake operation, depress and release the pedal several times while the engine is stopped. This eliminates vacuum from the system. Hold the brake down with moderate foot pressure and start the engine. If the power unit is operating properly, the brake pedal moves downward when the engine is started.

Master Cylinder Replacement To remove a master cylinder, disconnect the brake lines at the master cylinder. Install plugs in the brake lines and master cylinder to prevent dirt from entering. Remove the nuts that attach the master cylinder to the fire wall power brake unit and remove the cylinder.

Reassemble, install, and bleed the master cylinder according to the manufacturer's directions. Photo Sequence 48 is a typical procedure for bench bleeding a master cylinder.

Warning! Brake fluid can damage or even remove paint. Always use fender covers to protect the vehicle's finish and take extra care not to spill brake fluid under the hood on wiring or other components.

SHOP TALK

Master cylinders are seldom rebuilt; rather, they are replaced as a unit. In many cases rebuilding kits are not available for late-model vehicles, requiring the unit to be replaced.

Hydraulic System Bleeding

Fluids cannot be compressed, whereas gases are compressible. Any air in the brake hydraulic system is compressed as the pressure increases. This action reduces the amount of force that can be transmitted by the fluid, therefore it is very important to keep all air out of the hydraulic system. To do this, air must be bled from brakes. This procedure is called bleeding the brake system.

Bleeding is a process of forcing fluid through the brake lines and out through a bleeder valve or bleeder screw **(Figure 50–36)**. The fluid eliminates any air that might be in the system. Bleeder screws and valves are fastened to the wheel cylinders or calipers. Before attempting to open it, the bleeder should be cleaned. A drain hose then is connected from the bleeder to a glass jar **(Figure 50–37)**.

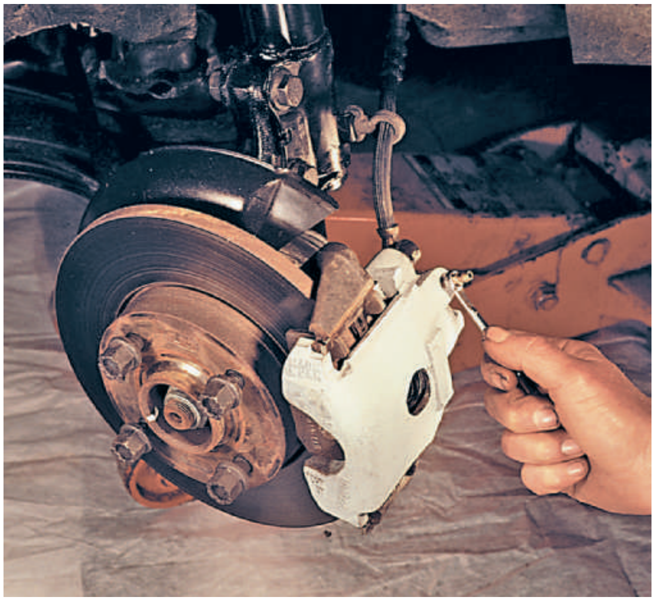

FIGURE 50–36 The wheel brake hydraulic units are fitted with bleeder screws.

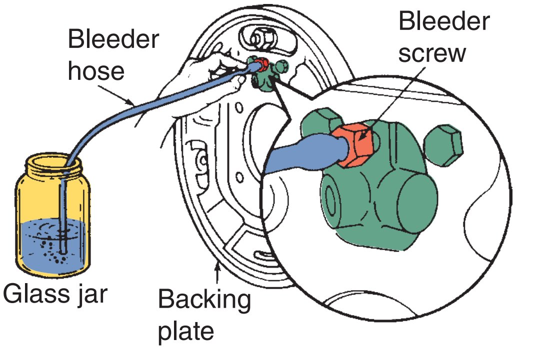

FIGURE 50–37 While bleeding the brake system, releasing the fluid into a glass jar will help to determine when the system is free of air.

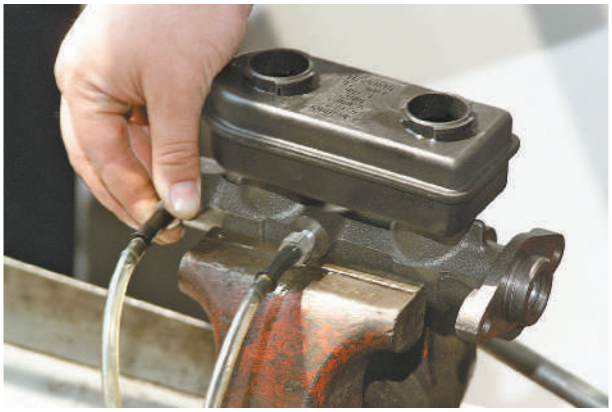
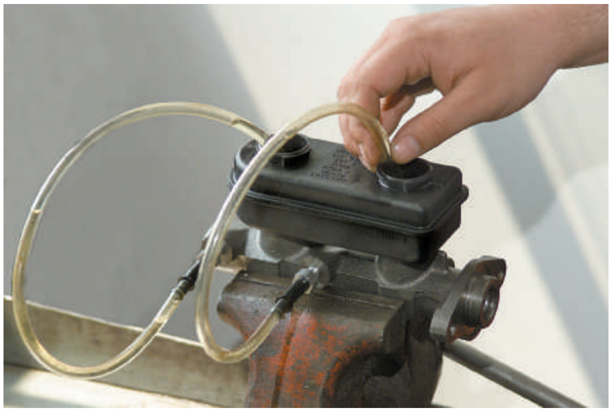
Typical Procedure for Bench Bleeding a Master Cylinder

P48-1 Mount the master cylinder firmly in a vise, being careful not to apply excessive pressure to the casting. Position the master cylinder so the bore is horizontal.



P48-2 Connect short lengths of tubing to the outlet ports, making sure the connections are tight.



P48-3 Bend the tubing lines so that the ends are in each chamber of the master cylinder reservoir.

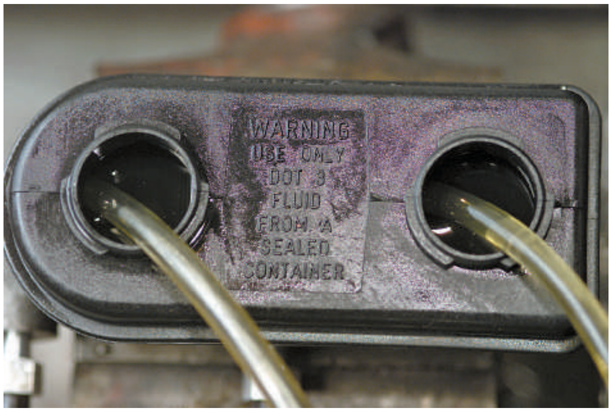
P48-4 Fill the reservoirs with fresh brake fluid until the level is above the ends of the tubes.

P48-5 Using a wooden dowel or the blunt end of a drift or punch, slowly push on the master cylinder pistons until both are completely bottomed out in their bore.

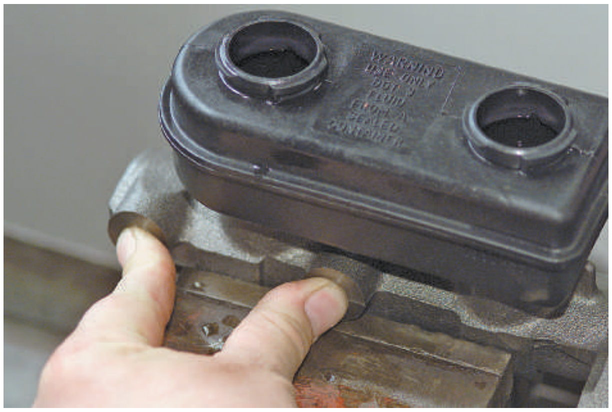
P48-6 Watch for bubbles to appear at the tube ends immersed in the fluid. Slowly release the cylinder piston and allow it to return to its original position. On quick take-up master cylinders, wait 15 seconds before pushing in the piston again. On other units, repeat the stroke as soon as the piston returns to its original position. Slow piston return is normal for some master cylinders.

PHOTO SEQUENCE 48

Typical Procedure for Bench Bleeding a Master Cylinder *(continued)*

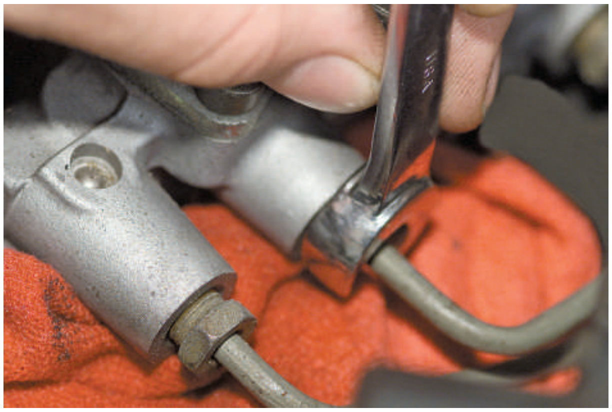


P48-7 Pump the cylinder piston until no bubbles appear in the fluid.



P48-8 Remove the tubes from the outlet ports and plug the openings with temporary plugs or your fingers. Keep the ports covered until you install the master cylinder on the vehicle.

P48-9 Install the master cylinder on the vehicle. Attach the lines, but do not tighten the tube connections.



P48-10 Slowly depress the pedal several times to force out any air that might be trapped in the connections each time the pedal is depressed. Before releasing the pedal, tighten the nut slightly and loosen it before depressing the pedal each time. Soak up the fluid with a rag to avoid damaging the car finish.

P48-11 When there are no air bubbles in the fluid, tighten the connections to the manufacturer's specifications. Make sure the master cylinder reservoirs are adequately filled with brake fluid.

P48-12 After reinstalling the master cylinder, bleed the entire brake system on the vehicle.

Two types of brake bleeding procedures are used: manual bleeding (including vacuum bleeding) and pressure bleeding. On some antilock brake systems, a scan tool is required to bleed the brakes. Always follow the manufacturer's recommendations when bleeding brakes. The sequence in which bleeding is performed can be critical. To remove vacuum from the vacuum-assist unit, the engine must be off, then pump the brake pedal several times.

Warning! Always use fresh brake fluid when bleeding the system. Do not use fluid that has already been opened. Do not use fluid that has been drained. Drained fluid may be contaminated and can damage the system.

Bleeding Sequence All manufacturers recommend a specific sequence to follow when bleeding a vehicle's brakes. These recommendations can be found in the service information and should be followed. If the manufacturer's recommendations are not available, the following sequence will work on most vehicles. This sequence starts at the wheel furthest from the master cylinder and works to the wheel closest:

1. Master cylinder
2. Combination valve or proportioning valve (if fitted with bleeder screws)
3. Right rear
4. Left rear
5. Right front
6. Left front
7. Height-sensing proportioning valve (if there is a bleeder screw)

Remember to stop after bleeding each wheel and refilling the fluid in the master cylinder. Failure to perform this step may result in running out of fluid and pulling air into the system.

This sequence is based on the principles of starting at the highest point in the system and working downward, then starting at the wheel farthest from the master cylinder and working to the closest. A couple of more general rules also are worth remembering.

If the brake system is split between the front and rear wheels, the rear wheels (which are farthest from the master cylinder) usually are bled first. If the brake system is split diagonally, the most common sequence is: RR-LF-LR-RF **(Figure 50–38)**. This sequence also applies to most systems with a quick take-up master cylinder. If you bleed a quick take-up

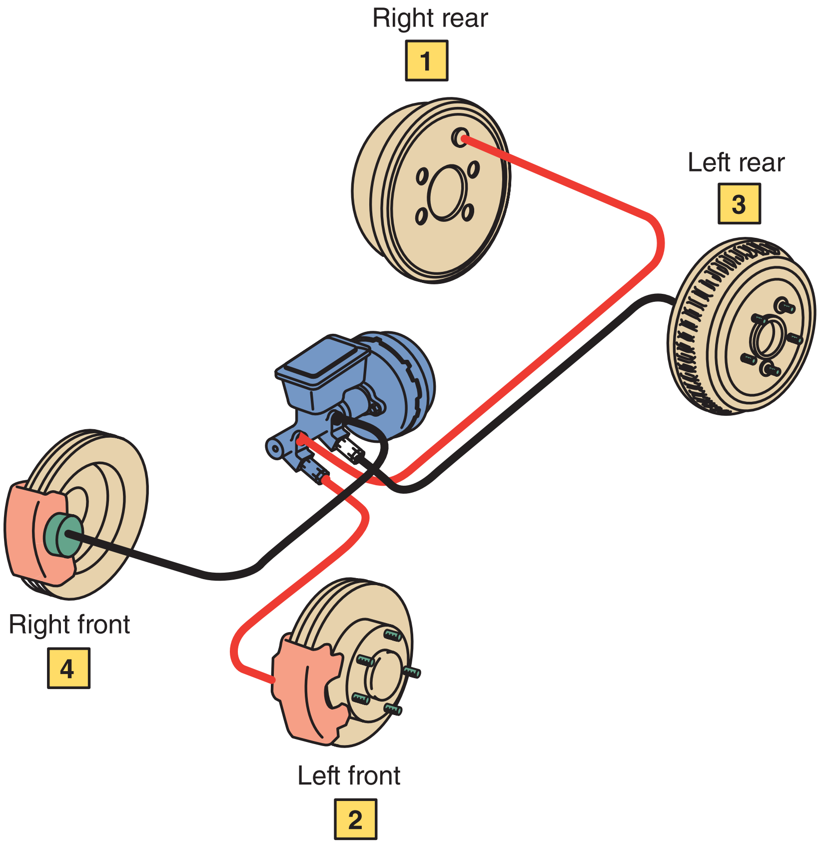


FIGURE 50–38 The recommended bleeding sequence for a diagonally split brake system.

system in any other sequence, you may chase air throughout the system.

Exceptions to the general rules exist, however. Chrysler, for example, recommends bleeding both rear brakes before the front brakes, regardless of how the hydraulic system is split.

Manual Bleeding A manual bleeding procedure requires two people. One person operates the bleeder; the other, the brake pedal. Bleed only one wheel at a time.

> **Warning!** Be sure the bleeder hose is below the surface of the liquid in the jar at all times. Do not allow the master cylinder to run out of fluid at any time. If these precautions are not followed, air can enter the system, and it must be bled again. The master cylinder cover must be kept in place.

Place the bleeder hose and jar in position. Have a helper pump the brake pedal several times and then hold it down with moderate pressure. Slowly open the bleeder valve. After fluid/air has stopped flowing, close the bleeder valve. Have the helper slowly release the pedal. Repeat this procedure until fluid that flows from the bleeder is clear and free of bubbles.

Discard all used brake fluid. Fill the master cylinder reservoir after bleeding each wheel brake. Check the brakes for proper operation.

> **Warning!** Clean the master cylinder and cover before adding fluid. This is important for preventing dirt from entering the reservoir.

Pressure Bleeding A pressure bleeding procedure can be done by one person. Pressure bleeding equipment uses pressurized fluid that flows through a special adapter fitted into the master cylinder **(Figure 50–39)**.

The use of pressure bleeding equipment varies with different automobiles and different equipment makers. Always follow the automobile manufacturer's recommendations when using pressure bleeding equipment.

On automobiles with metering valves, the valve must be held open during pressure bleeding. A special tool is used to hold open the metering section of a combination valve.

> **USING SERVICE INFORMATION**
> Consult the service information to be sure that the proper bleeding sequence is followed. If a vehicle requiring a special sequence is bled in the conventional manner, air might be chased throughout the system.

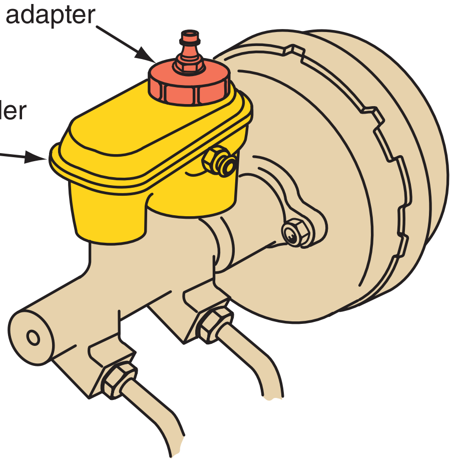

FIGURE 50–39 An adapter that installs onto the reservoir's fill opening is required to pressure bleed the brake system.

Open the bleeder valves one at a time until clear, air-free fluid is flowing. Progress from the wheel cylinder farthest from the master cylinder to the cylinder closest.

Do not exceed recommended pressure while bleeding the brakes. Always release air pressure after bleeding. Clean and fill the master cylinder after pressure bleeding. Check the brakes for proper operation. Be sure to remove the special tool used to hold the metering valve.

Power Brakes

Power brakes are nothing more than a standard hydraulic brake system with a booster unit located between the brake pedal and the master cylinder to help activate the brakes.

Three basic types of power-assist mechanisms are used. The first is vacuum assist. These systems use engine vacuum, or sometimes vacuum pressure developed by an external vacuum pump, to help apply the brakes. The second type of power assist is hydraulic assist. It is normally found on larger vehicles.

This system uses hydraulic pressure developed by the power steering pump or other external pump to help apply the brakes. The third type is a function of integral ABS units that combine the master cylinder, power assist, and ABS into one assembly.

Both vacuum and hydraulic assist act to multiply the force exerted on the master cylinder pistons by the driver. This increases the hydraulic pressure delivered to the wheel cylinders or calipers while decreasing driver foot pressure. Integral ABS units use an electric pump to provide pressure for brake assist and ABS functions.

GO TO Go to Chapter 53 for more on ABS operation.

Vacuum-Assist Power Brakes

All vacuum-assisted units are similar in design. They generate application energy by opposing engine vacuum to atmospheric pressure. A piston and cylinder, flexible diaphragm, or bellows use this energy to provide braking assistance.

All modern vacuum-assist units are vacuum-suspended systems. This means the diaphragm inside the unit is balanced using engine vacuum until the brake pedal is depressed. Applying the brake allows atmospheric pressure to unbalance the diaphragm and allows it to move generating application pressure.

Atmospheric pressure is normally between 14 and 15 psi (96.5 and 103 kPa). If the diameter of the diaphragm is 12 inches (305 mm), the area of the diaphragm is about 113 square inches (72,907 sq. mm). Since the vacuum to the booster is typically 17 inches of mercury (432 mm Hg) or about 7 psi (48 kPa), the pressure differential on the diaphragm is 7.7 psi (53 kPa). Therefore, the resulting force on the diaphragm would be 870 pounds (3870 N) (7.7×113).

Vacuum boosters may be single diaphragm or tandem diaphragm. The unit consists of three basic elements combined into a single power unit **(Figure 50–40)**.

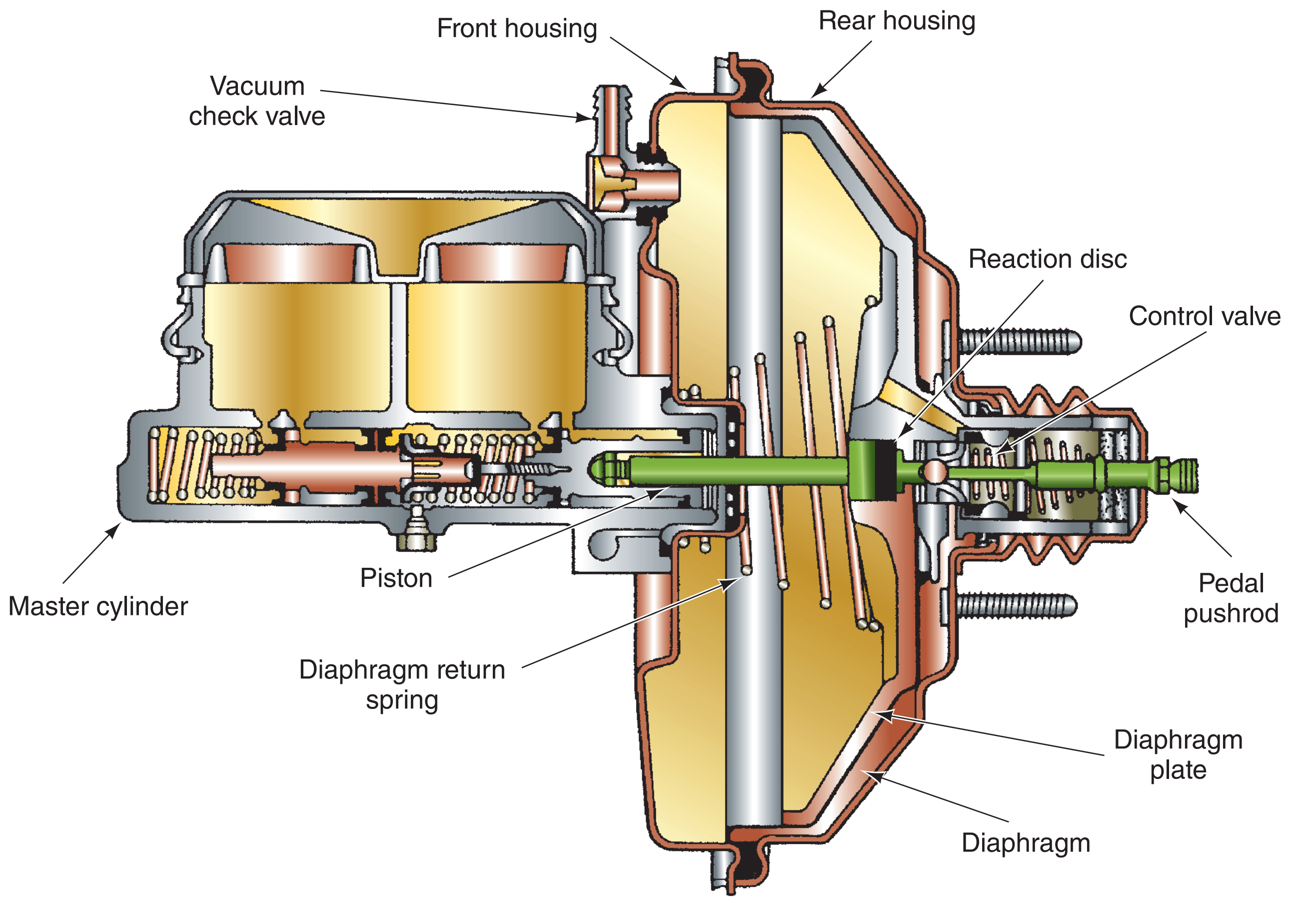

FIGURE 50–40 A typical vacuum brake booster.

The three basic elements of the single diaphragm follow:

1. A vacuum power section that includes a front and rear shell, a power diaphragm, a return spring, and a pushrod.
2. A control valve built as an integral part of the power diaphragm and connected through a valve rod to the brake pedal. It controls the degree of brake application or release in accordance with the pressure applied to the brake pedal.
3. A hydraulic master cylinder, attached to the vacuum power section that contains all the elements of the conventional brake master cylinder except for the pushrod. It supplies fluid under pressure to the pressure applied by the brake booster.

Operation When the brakes are applied, the valve rod and plunger move to the left in the power diaphragm. This action closes the control valve's vacuum port and opens the atmospheric port to admit air through the valve at the rear diaphragm chamber **(Figure 50–41)**. With vacuum in the rear chamber, a force develops that moves the power diaphragm, hydraulic pushrod, and hydraulic piston or pistons to close the compensating port or ports and force fluid under pressure through the residual check valve or valves and lines into the front and rear brake assemblies.

As pressure develops in the master cylinder, a counterforce acts through the hydraulic pushrod and reaction disc against the vacuum power diaphragm and valve plunger. This force tends to close the atmospheric port and reopen the vacuum port. Since this force is in opposition to the force applied to the brake pedal by the operator, it gives the operator a feel for the amount of brake applied.

Servicing Vacuum-Assist Booster Units The fact that a vehicle's brakes still operate when the vacuum-assist unit fails indicates that the hydraulic brake system and the vacuum-assist system are two separate systems. This means you should always check for faults in the hydraulic system first. If it checks out satisfactorily, start inspecting the vacuum-assist circuit.

For a fast check of vacuum-assist operation, press the brake pedal firmly and then start the engine.

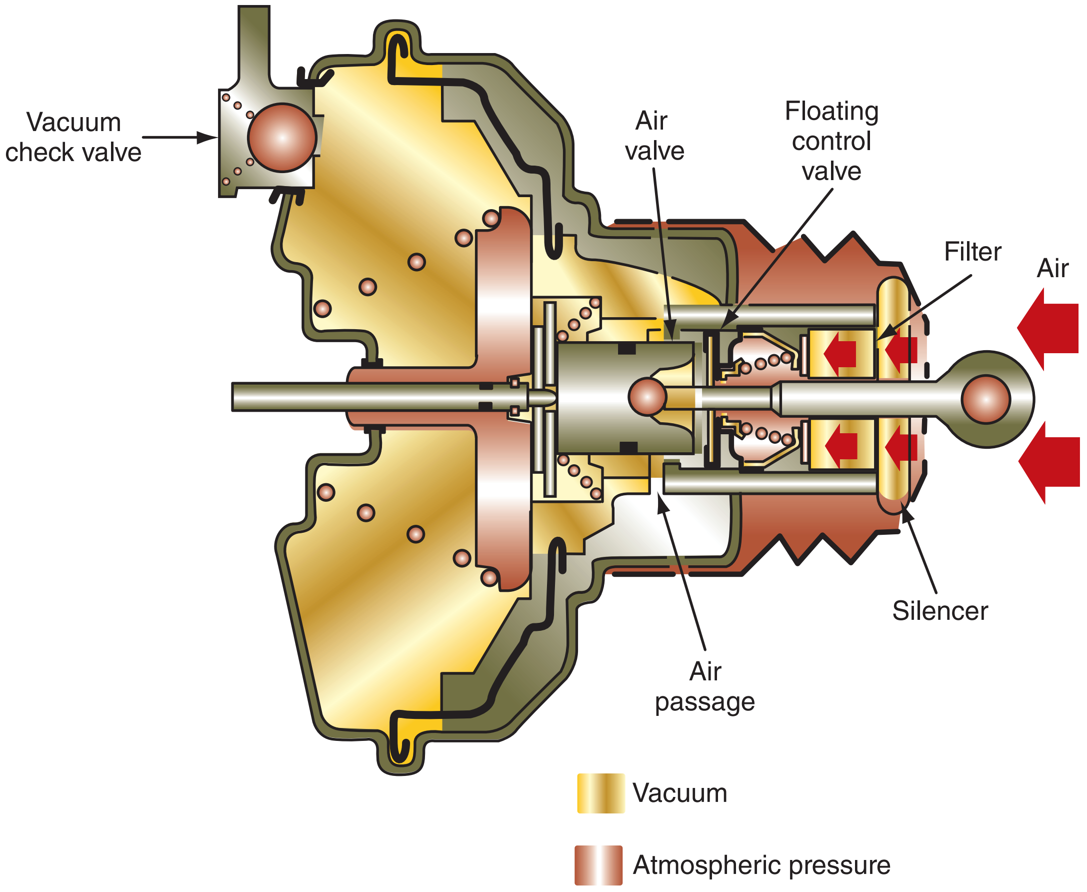

FIGURE 50–41 When the brakes are applied, atmospheric air pressure moves the diaphragm and piston forward, increasing the force applied to the pushrod.

The pedal should fall away slightly and less pressure should be needed to maintain the pedal in any position. This also checks the vacuum booster's check valve's operation. The pedal should be easy to press at least once or twice and then get very firm. If the check valve is not working, the pedal will be very hard to press the first time after the engine is off.

Some vehicles have a brake booster diaphragm position sensor, that if faulty, can set chassis system DTCs and pedal feel concerns. When testing a vacuum booster for a hard or soft/low pedal, check for DTCs and for proper sensor operation.

Pressure Check. Another simple check can be made by installing a suitable pressure gauge in the brake hydraulic system. Take a reading with the engine off and the power unit not operating. Maintain the same pedal height, start the engine, and read the gauge. There should be a substantial pressure increase if the vacuum-assist booster is operating correctly.

Pedal Travel. Pedal travel and total travel are critical on vacuum-assisted vehicles. Pedal travel should be kept strictly to specifications listed in the vehicle's service information.

Vacuum Reading. If the power unit is not giving sufficient assistance, take a manifold vacuum reading. If manifold vacuum level is below specifications, tune the engine and retest the unit. Loose or damaged vacuum lines and clogged air intake filters reduce braking assistance. Most units have a check valve that retains some vacuum in the system when the engine is off. A vacuum gauge check of this valve indicates if it is restricted or stays open.

Release Problems. Failure of the brakes to release is often caused by a tight or misaligned connection between the power unit and the brake linkage. Broken pistons, diaphragms, bellows, or return springs can also cause this problem.

To help pinpoint the problem, loosen the connection between the master cylinder and the brake booster. If the brakes release, the problem is caused by internal binding in the vacuum unit. If the brakes do not release, look for a crimped or restricted brake line or similar problem in the hydraulic system.

Hard Pedal. Power brakes that have a hard pedal may have collapsed or leaking vacuum lines of insufficient manifold vacuum. Punctured diaphragms or bellows and leaky piston seals all lead to weak power unit operation and hard pedal. A steady hiss when the brake is held down indicates a vacuum leak that causes poor operation.

Grabbing Brakes. First, look for the common causes of brake grab, such as greasy linings, or scored rotors or drums. If the trouble appears to be in the power unit, check for a damaged reaction control. The reaction control is made up of a diaphragm, spring, and valve that tend to resist pedal action. It is put into the system to give the driver more brake pedal feel.

Check of Internal Binding. Release problems, hard pedal, and dragging (slow releasing) brakes can all be caused by internal binding. To test a vacuum unit for internal binding, place the transmission/transaxle in neutral and start the engine. Increase engine speed to 1,500 rpm, close the throttle, and completely depress the brake pedal. Slowly release the brake pedal and stop the engine. Remove the vacuum check valve and hose from the vacuum-assist unit. Observe for backward movement of the brake pedal. If the brake pedal moves backward, there is internal binding and the unit should be replaced.

Pushrod Adjustment

Proper adjustment of the master cylinder pushrod is necessary to ensure proper operation of the power brake system. A pushrod that is too long causes the master cylinder piston to close off the vent port, preventing hydraulic pressure from being released and resulting in brake drag. A pushrod that is too short causes excessive brake pedal travel and causes groaning noises to come from the booster when the brakes are applied. A properly adjusted pushrod that remains assembled to the booster with which it was matched during production should not require service adjustment. However, if the booster, master cylinder, or pushrod are replaced, the pushrod might require adjustment.

Two methods can be used to check for proper pushrod length and installation: the gauge method and the air method.

Gauge Method

In most vacuum power units, the master cylinder pushrod length is fixed, and length is usually checked only after the unit has been overhauled or replaced. A typical adjustment using the gauge method is shown in **Figure 50–42**.

Air Method

The air-testing method uses compressed air applied to the hydraulic outlet of the master cylinder. Air

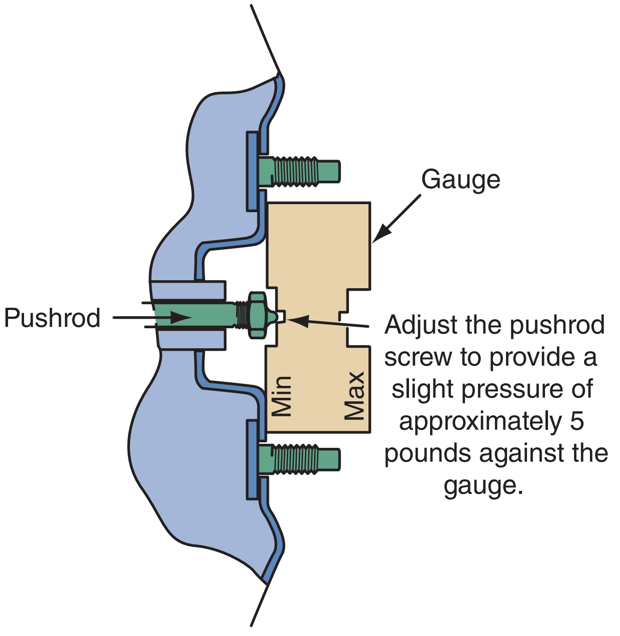

FIGURE 50-42 A gauge for measuring pushrod length.

pressure is regulated to a value of approximately 5 psi (35 kPa) to prevent brake fluid spraying from the master cylinder.

If air passes through the replenishing port, which is the smaller of the two holes in the bottom of the master cylinder reservoir, the adjustment is satisfactory. If air does not flow through the replenishing port, adjust the pushrod as required, either by means of the adjustment screw (if provided) or by adding shims between the master cylinder and power unit shell until the air flows freely.

Hydraulic Brake Boosters

Decreases in engine size, plus the continued use of engine vacuum to operate other engine systems, such as emission control devices, led to the development of hydraulic-assist power brakes. These systems use fluid pressure, not vacuum pressure, to help apply the brakes. They are mostly found on diesel engines and other engines that have low vacuum.

Fluid pressure from the power-steering pump provides the power assist to the brakes. The power brake booster is located between the cowl and the master cylinder. Hoses connect the power-steering pump to the booster assembly.

The power-steering pump provides a continuous flow of fluid to the brake booster whenever the engine is running. Three flexible hoses route the power-steering fluid to the booster. One hose supplies pressurized fluid from the pump. Another hose routes the pressurized fluid from the booster to the power-steering gear assembly. The third hose returns fluid from the booster to the power-steering pump.

The hydraulic pressure in the hydraulic booster should not be confused with the hydraulic pressure in the brake lines. Remember that they are two separate systems and require two different types of fluid: power-steering fluid for the pump and brake fluid for the brake system. Never put power-steering fluid in the brake reservoir. If the brake fluid becomes contaminated by power-steering fluid, the rubber components will be damaged. This may require the replacement of all parts that contain rubber and the steel lines of the brake system will need to be flushed.

Some systems have a nitrogen charged pneumatic accumulator on the booster to provide reserve power-assist pressure. If power-steering pump pressure is not available due to belt failure or similar problems, the accumulator pressure is used to provide brake assist.

The booster assembly **(Figure 50–43)** consists of an open center spool valve and sleeve assembly, a lever assembly, an input rod assembly, a power piston, an output pushrod, and the accumulator. The booster assembly is mounted on the vehicle in much the same manner as a vacuum booster. The pedal rod is connected at the booster input rod end.

Power-steering fluid flow in the booster unit is controlled by a hollow center spool valve. The spool valve has lands, annular grooves, and drilled passages. These mate with grooves and lands in the valve bore. The flow pattern of the fluid depends on the alignment of the valve in the bore.

Operation

When the brake pedal is depressed, the pedal's pushrod moves the master cylinder's primary piston forward. This causes the lever assembly of the booster to move a sleeve forward to close off the holes leading to the open center of the spool valve. A small additional lever movement moves the spool valve into the spool valve bore. The spool valve then diverts some hydraulic fluid into the cavity behind the booster piston building up hydraulic pressure that moves the piston and a pushrod forward. The output pushrod moves the primary and secondary master cylinder pistons that apply pressure to the brake system. When the brake pedal is released, the spool and sleeve assemblies return to

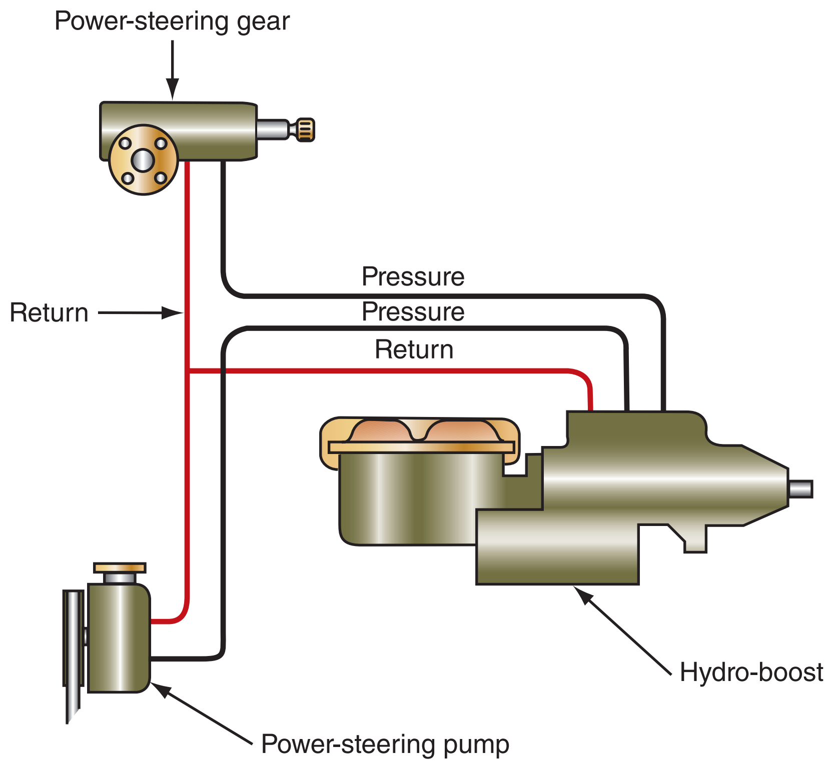

FIGURE 50–43 A hydraulic brake booster.

their normal positions. Excess fluid behind the piston returns to the power-steering pump reservoir through the return line. After the brakes have been released, pressurized fluid from the power-steering pump flows into the booster through the open center of the spool valve and back to the power-steering pump.

There have been many variations of and names given to hydraulic brake booster systems. The most common names are the hydro-boost system produced by Bendix and the Powermaster system produced by General Motors. The Powermaster system is a little different from the rest in that it uses a self-contained hydraulic booster that is built directly onto the master cylinder. Instead of relying on the power-steering pump for hydraulic pressure as is done in the other systems, the Powermaster has its own vane pump and electric motor to provide the hydraulic pressure required for booster operation.

Any investigation of a hydraulic boost complaint should begin with an inspection of the power-steering pump belt, fluid level, and hose condition and connections. Hydraulic boost systems do not work properly if they are not supplied with a continuous supply of clean, bubble-free power-steering fluid at the proper pressure.

Warning! Always depressurize the accumulator of any hydraulic boost system before disconnecting any brake lines or hoses. This is usually done by turning the engine off and depressing and releasing the brake pedal up to ten times.

Basic Operational Test

The basic operational test of these systems is as follows. With the engine off, pump the brake pedal numerous times to bleed off the residual hydraulic pressure that is stored in the accumulator. Hold firm pressure on the brake pedal and start the engine. The brake pedal should move downward, then push up against the foot.

Accumulator Test

To be sure the accumulator is performing properly, rotate the steering wheel with the engine running until it stops and hold it in that position for no more than 5 seconds. Return the steering wheel to the center position and shut off the engine. Pump the

brake pedal. You should feel two to three power-assisted strokes. Now repeat the steps. That pressurizes the accumulator. Wait one hour, then pump the brake pedal. There should be two or three power-assisted strokes. If the system does not perform as just described, the accumulator is leaking and should be replaced.

Noise Troubleshooting

The booster is also part of another major subsystem of the vehicle, the power-steering system. Problems or malfunctions in the steering system may affect brake-assist operation. The following are some common troubleshooting tips.

Moan or low-frequency hum usually accompanied by a vibration in the pedal or steering column might be encountered during parking or other very low-speed maneuvers. This can be caused by a low fluid level in the power-steering pump, or by air in the power-steering fluid due to holding the pump at relief pressure (steering wheel held all the way in one direction) for an excessive amount of time (more than 5 seconds). Check the fluid level and add fluid if necessary. Allow the system to sit for 1 hour with the cap removed to eliminate the air. If the condition persists, it might be a sign of excessive pump wear. Check the pump according to the vehicle manufacturer's recommended procedure.

At or near power runout (brake pedal near fully depressed position), a high-speed fluid noise (like a faucet can make) might occur. This is a normal condition and will not be heard, except in emergency braking conditions.

Whenever the accumulator pressure is used, a slight hiss is noticed. It is the sound of the hydraulic fluid escaping through the accumulator valve and is completely normal.

After the accumulator has been emptied and the engine is started again, another hissing sound might be heard during the first brake application or the first steering maneuver. This sound is caused by the fluid rushing through the accumulator charging orifice. It is normal and will only be heard once after the accumulator is emptied. However, if this sound continues even though no apparent accumulator pressure assist was made, it could indicate that the accumulator is not holding pressure. Check for this possibility using the accumulator test discussed previously.

After bleeding, a gulping sound might be present during brake applications, as noted in the bleeding instructions. This sound is normal and should disappear with normal driving and braking.

Diagnosis and testing of the Powermaster unit requires the use of a special adapter and test gauge or aftermarket equivalents. The Powermaster pressure switch is removed and the adapter and test gauge is installed in its port. The unit can then be energized, and the switch's high-pressure cut-off and low-pressure turn-on points observed and checked against specifications. Follow the instructions given in the service information for the connection and operation of the test gauge and all system test procedures.

Electric Parking Brakes

Electrically operated parking brakes are becoming more common and are replacing mechanical systems. These systems operate as a conventional hydraulic brake for normal braking and as an electric brake for parking. With electric parking brakes, there is no need for a parking brake lever or pedal. This frees up space in the interior.

Electric parking brakes are seen as the first step toward brake-by-wire systems. Two different techniques are currently being used by manufacturers. Some systems have an electric motor mounted on the rear brake calipers and others use an undercar motor to pull on the parking brake cables.

When the caliper is fitted with a motor **(Figure 50–44)**, there is no need for parking brake cables and linkages. The motor is controlled by the PCM. The system interfaces with the vehicle's controller area network (CAN) for continuous monitoring and feedback. This allows the system to do many things besides apply the parking brake, such as:

- Provide some control during emergency braking.
- Help stop the car if the hydraulic system fails.
- Automatically release the parking brakes when the throttle is opened.
- Automatically engage when the ignition is turned off.
- Automatically engage when the driver's door is opened.
- Keep the vehicle from rolling backward when stopped on a hill by applying the rear brakes until the driver operates the clutch or throttle pedals.

SUMMARY

- The four factors that determine a vehicle's braking power are pressure, which is provided by the hydraulic system; coefficient of friction, which represents the frictional relationship between pads and rotors or shoes and drums; frictional contact surface, which means bigger brakes stop a car more quickly than smaller brakes; and head dissipation, which is necessary to prevent brake fade.
- Today's brake linings are fully metallic, semimetallic, nonasbestos organic, synthetic, carbon, or ceramic.
- Since 1967, all cars have been required to have two separate brake systems. The dual brake system uses a tandem master cylinder, which is two master cylinders with two separated pistons and fluid reservoirs in one cylinder bore.
- The brake lines transmit brake fluid pressure from the master cylinder to the wheel cylinders and calipers of drum and disc brakes. Brake hoses offer flexible connections to wheel units and must offer high heat resistance.
- A pressure differential valve is used in all dual brake systems to operate a warning light switch that alerts the driver if pressure is lost in either hydraulic system.
- The metering valve, located in the front brake line, provides for better balance of the front and rear brakes while also preventing lockup of the front brakes.
- The proportioning valve controls rear brake pressure, particularly during hard stops.
- Bleeding removes air from the hydraulic system.
- Flushing removes old brake fluid from the system and replaces it with fresh new fluid. This should be done about every 2 years.
- Power brakes can be either vacuum assist or hydraulic assist. Vacuum-assisted units use engine vacuum or vacuum developed by an external pump to help apply the brakes. Hydraulic-assisted units use fluid pressure.

DRUM BRAKES

For many years, drum brakes **(Figure 51–1)** were used on all four wheels on virtually every vehicle on the road. Today, disc brakes have replaced drum brakes on the front wheels of most vehicles and some models are equipped with both front and rear disc brakes. One reason for their continued use is that drum brakes can easily handle the 20 percent to 40 percent of total braking load placed on the rear wheels. Another is that drum brakes can also be built with a simple parking brake mechanism.

Drum Brake Operation

Drum brake operation is fairly simple. The most important feature contributing to the effectiveness of the braking force supplied by the drum brake is the brake shoe pressure or force directed against the drum **(Figure 51–2)**. With the vehicle moving in either the forward or reverse direction with the brakes on, the applied force of the brake shoe pressing against the brake drum increasingly multiplies itself

(called self-energizing) because the brake's anchor pin acts as a brake shoe stop and prohibits the brake shoe from its tendency to follow the movement of the rotating drum. The result is a wedging action between the brake shoe and brake drum. The wedging action combined with the applied brake force creates a self-multiplied brake force.

Drum Brake Components

The **backing plate** provides a foundation for the brake shoes and associated hardware **(Figure 51–3)**. The plate is secured and bolted to the axle flange or spindle. The wheel cylinder,

FIGURE 51–3 The backing plate provides a foundation for the brake shoes and associated hardware.

under hydraulic pressure, forces the brake's shoes against the drum. There are also two linked brake shoes attached to the backing plate. Brake shoes are the backbone of a drum brake. They must support the lining and carry it into the drum so the pressure is distributed across the lining surface during brake application. Shoe return springs and shoe holddown parts maintain the correct shoe position and clearance. Some drum brakes are self-adjusting. Others require manual adjustment mechanisms. Brake drums provide the rubbing surface area for the linings. Drums must withstand high pressures without excessive flexing and must also dissipate large quantities of heat generated during brake application. Finally, the rear drum brakes on most vehicles include the parking brakes.

Wheel Cylinders

Wheel cylinders convert hydraulic pressure from the master cylinder into a mechanical force at the brakes **(Figure 51–4)**. The wheel cylinder bore is filled with fluid. When the brake pedal is depressed, additional brake fluid is forced into the cylinder. The additional fluid moves the cups and pistons outward. This piston movement forces the brake shoes outward to the contact drum and thus applies the brakes. Piston stops prevent the fluid leakage or air from getting into the system when the pistons move to the end of their bores.

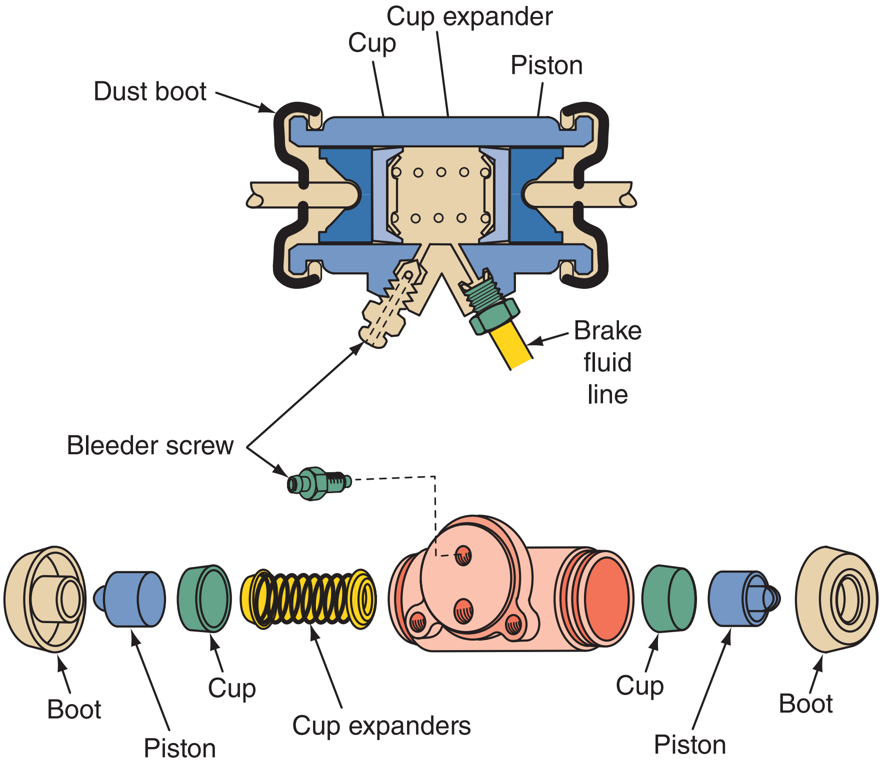

FIGURE 51–4 The exploded view of a typical wheel cylinder.

Brake Shoes and Linings

In the same brake shoe sizes, there can be differences in **web** thickness, shape of web cutouts, and positions of any reinforcements **(Figure 51–5)**.

The shoe rim is welded to the web to provide a stable surface for the lining. The web thickness might differ to provide the stiffness or flexibility needed for a specific application. Many shoes have nibs or indented places along the edge of the rim.

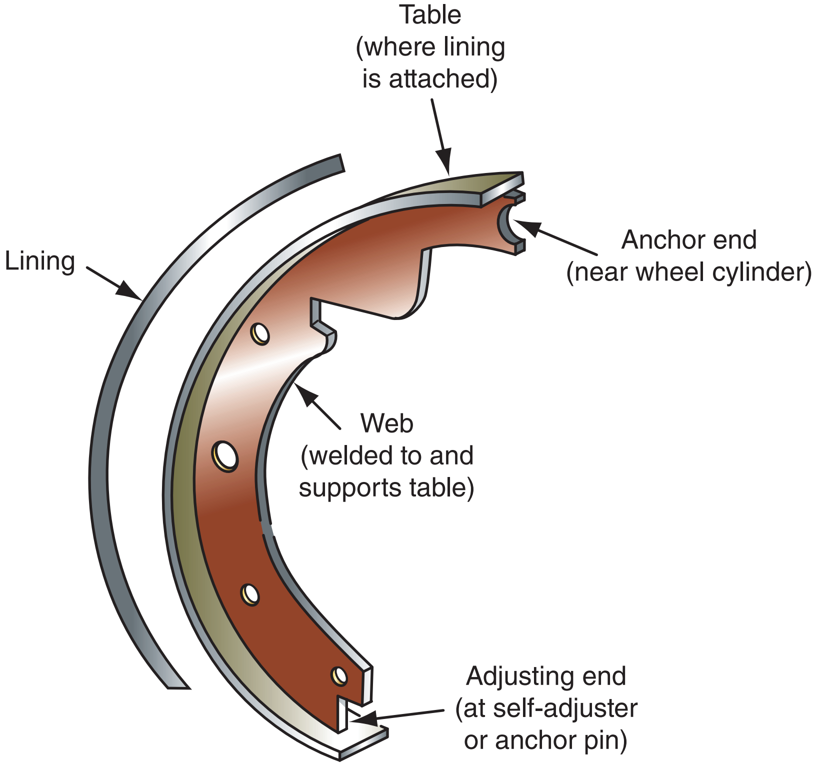

FIGURE 51–5 A typical brake shoe with the lining detached.

These nibs rest against shoe support ledges on the backing plate and keep the shoe from hanging up.

Each drum in the drum braking system contains a set of shoes. In a servo system, the **primary shoe** (or leading shoe) is the one that is toward the front of the vehicle. The friction between the primary shoe and the brake drum forces the primary shoe to shift slightly in the direction that the drum is turning. (An anchor pin permits limited movement.) The shifting of the primary shoe forces it against the bottom of the secondary shoe, which causes the secondary shoe to contact the drum. The **secondary shoe** (or trailing shoe) is the one that is toward the rear of the vehicle. It comes into contact as a result of the movement and pressure from the primary shoe and wheel cylinder piston and increases the braking action **(Figure 51–6)**.

The brake shoe lining provides friction against the drum to stop the car. It contains heat-resistant fibers. The lining is molded with a high-temperature synthetic bonding agent.

The two general methods of attaching the lining to the shoe are riveting and bonding. Regardless of the method of attachment, brake shoes are usually held in a position by spring tension. They are either held against the anchor by the shoe return springs or against the support plate pads by shoe **holddown springs**. The shoe webs are linked together at the end opposite the anchor by an adjuster and a spring. The adjuster holds them apart. The spring holds them against the adjuster ends.

Mechanical Components

In the unapplied position, the shoes are held against the anchor pin by the return springs. The shoes are held to the backing plate by holddown springs or spring clips. Opposite the anchor pin, an adjuster links the shoe webs and provides an adjustment that permits the shoes to be expanded or contracted. The shoes are held against the adjuster by a spring.

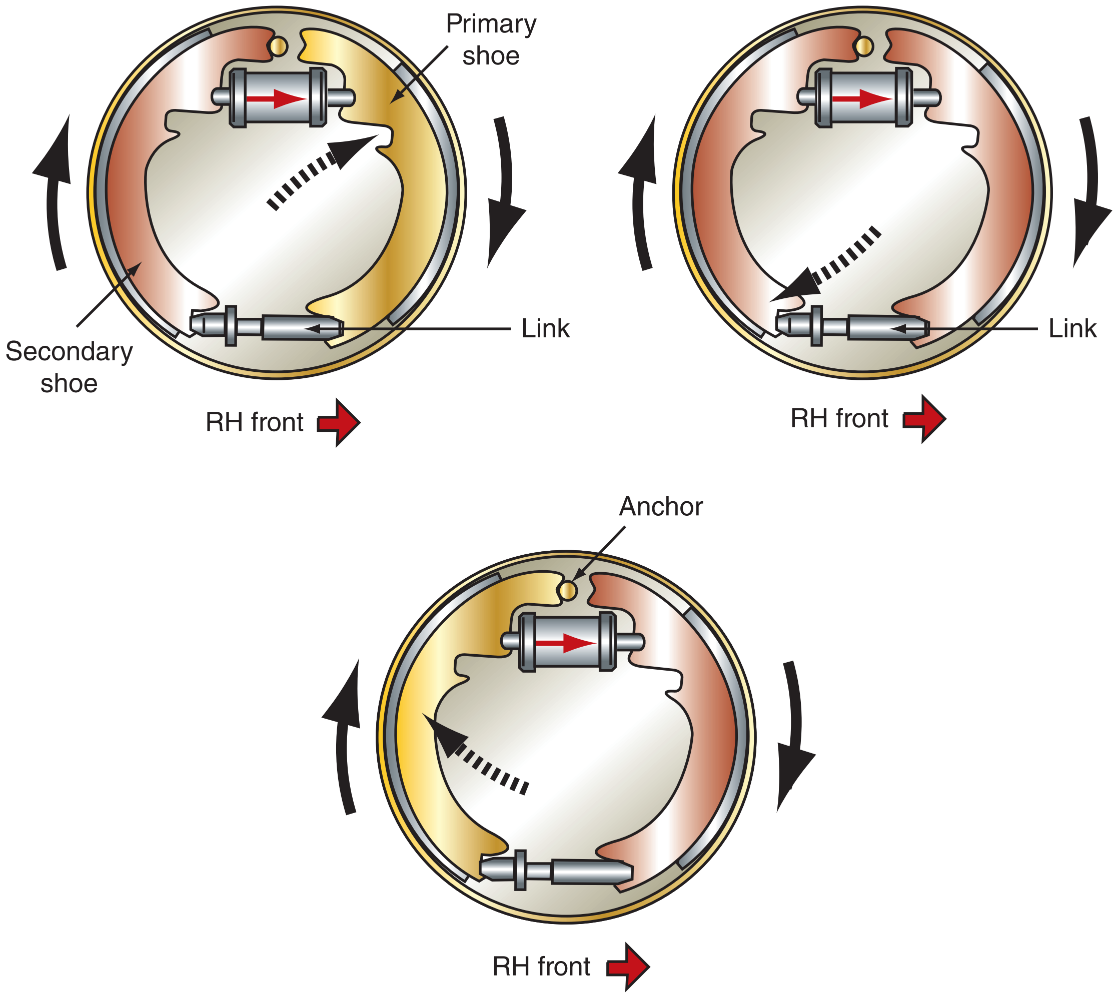

FIGURE 51–6 In a servo brake system, the self-energizing action of the primary shoe applies force to the secondary shoe.

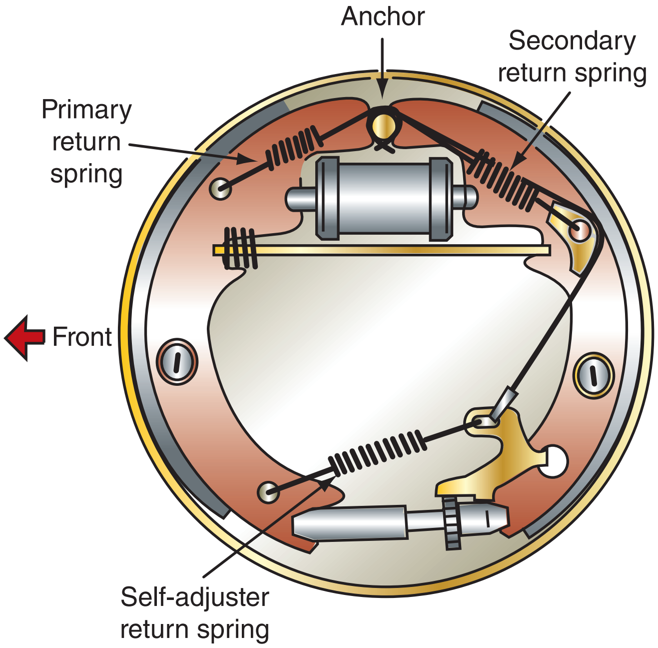

FIGURE 51–7 Typical return spring installation in a duo-servo system.

Shoe Return Springs **Return springs** can be separately hooked into a link or a guide or strung between the shoes. Springs are normally installed on the anchor with servo type brakes as shown in **Figure 51–7**. In nonservo brake assemblies, the return springs typically connect each shoe together as shown in **Figure 51–8**.

While shoe brake springs look the same, they are usually not interchangeable. Sometimes to help distinguish between them, they are color coded. Pay close attention to the colors and the way they are hooked up.

Shoe Holddowns Various shoe holddowns are illustrated in **Figure 51–9**. To unlock or lock the straight pin holddowns, depress the locking cup and coil

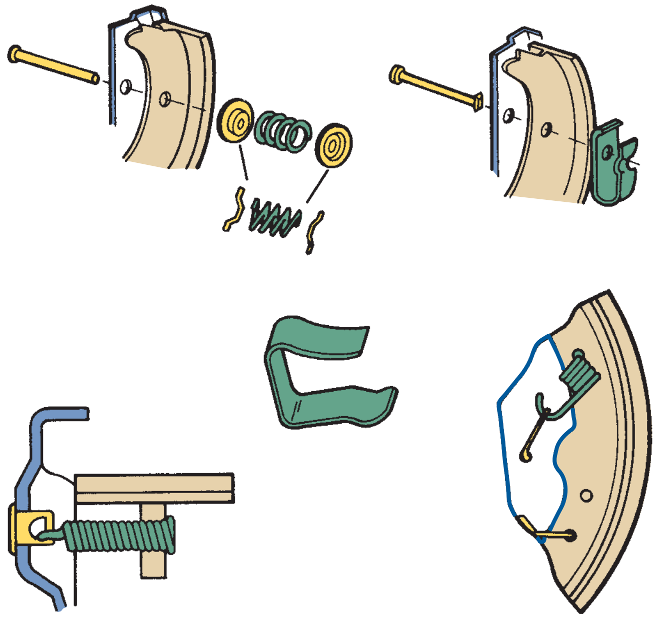

FIGURE 51–9 Types of brake shoe holddowns.

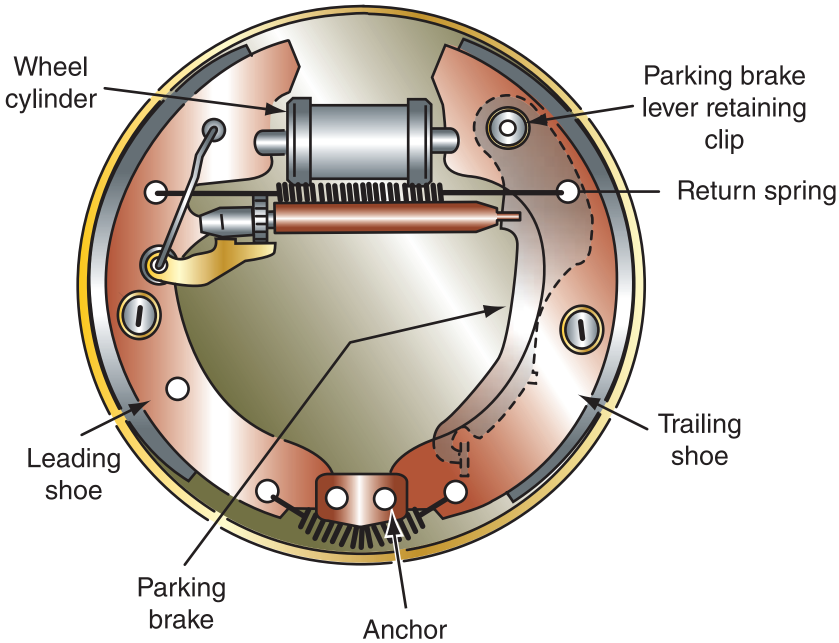

FIGURE 51–8 In nonservo systems, the return springs typically connect each brake shoe together.

spring or the spring clip, and rotate the pin or lock 90 degrees. On General Motors' lever adjusters, the inner (bottom) cup has a sleeve that aligns the adjuster lever.

Shoe Anchors There are various types of **shoe anchors** such as the fixed nonadjustable type, self-centering shoe sliding type, or on some earlier models, adjustable fixed-type providing either an eccentric or a slotted adjustment. On some front brakes, fixed anchors are threaded into or are bolted through the steering knuckle and also support the wheel cylinder.

Drums

Modern automotive brake drums are made of heavy cast iron (some are aluminum with an iron or steel sleeve or liner) with a machined surface inside against which the linings on the brake shoes generate friction when the brakes are applied. This results in the creation of a great deal of heat. The inability of drums to dissipate as much heat as disc brakes is one of the main reasons discs have replaced drums at the front of all late-model cars and light trucks, and at the rear of some sports and luxury cars.

Sometimes the rear drums of FWD cars and larger trucks are integral with the hub and cannot be removed without disassembling the wheel bearing. These are called fixed drums as they are held or fixed in place by other components **(Figure 51–10)**. The rear drums of other FWD and most RWD cars are held in place by the wheel lugs so they can be removed without tampering with the wheel bearings. These are called floating drums.

Drum Brake Designs

There are two brake designs in common use. They are duo-servo (or self-energizing) drum brakes and nonservo (or leading-trailing) drum brakes.

Most large American cars use the duo-servo design of brake. However, the nonservo type has become popular as the size of cars has become smaller. Because the smaller cars are lighter, this type of brake helps reduce rear brake lockup without reducing braking ability.

Duo-Servo Drum Brakes

The name **duo-servo drum brake** is derived from the fact that the **self-energizing force** is transferred from one shoe to the other with the wheel rotating in either direction. Both the primary (front) and secondary (rear) brake shoes are actuated by a double-piston wheel cylinder. The upper end of each shoe is held against a single anchor by a heavy coil return spring. An adjusting screw assembly and spring connect the lower ends of the shoes.

The wheel cylinder is mounted on the backing plate at the top of the brake. When the brakes are applied, hydraulic pressure behind the wheel cylinder cups forces both pistons outward causing the brakes to be applied.

When the brake shoes contact the rotating drum in either direction of rotation, they tend to move with the drum until one shoe contacts the anchor and the other shoe is stopped by the star wheel adjuster link **(Figure 51–11)**. With forward rotation, frictional forces between the lining and the drum of the primary shoe

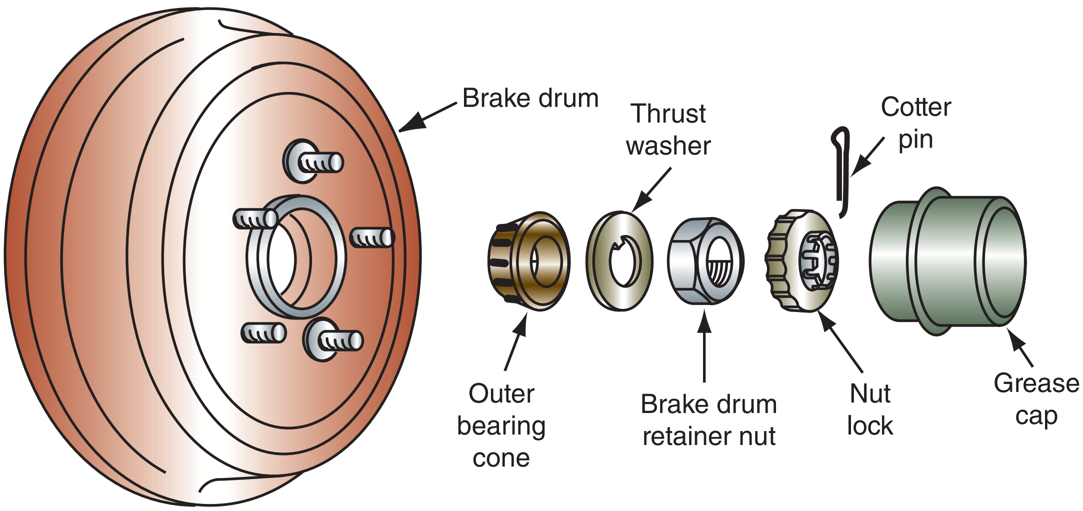

FIGURE 51–10 To remove a fixed drum assembly, remove the retaining nut and slide the assembly off with its bearings.

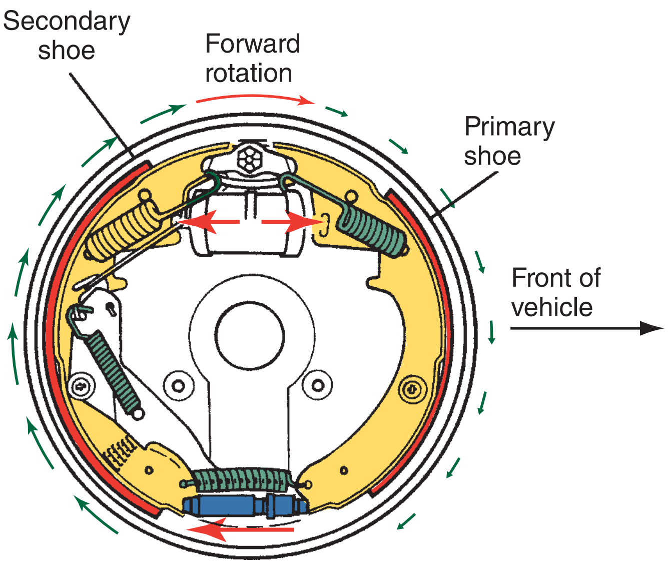

FIGURE 51–11 Duo-servo braking forces.

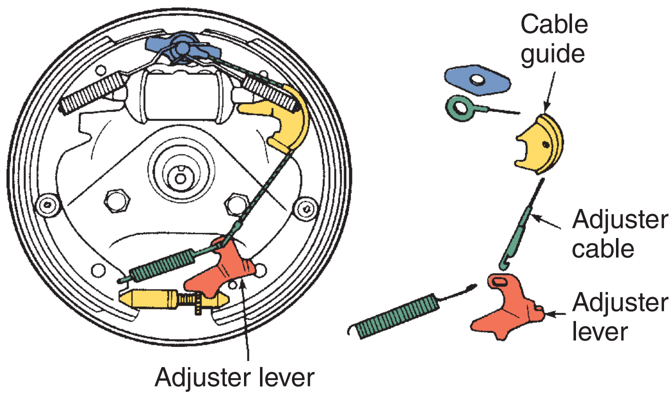

FIGURE 51–12 Cable self-adjusters.

result in a force acting on the adjuster link to apply the secondary shoe. This adjuster link force into the secondary shoe is many times greater than the wheel cylinder input force acting on the primary shoe. The force of the adjuster link into the secondary shoe is again multiplied by the frictional forces between the secondary lining and rotating drum, and all of the resultant force is taken on the anchor pin. In normal forward braking, the friction developed by the secondary lining is greater than the primary lining. Therefore, the secondary brake lining is usually thicker and has more surface area. The roles of the primary and secondary linings are reversed in braking the vehicle when backing up.

Automatically Adjusted Duo-Servo Brakes

Since the early 1960s, automatic drum brake adjusters have been used on all American and most import vehicles. There are several variations of automatic adjusters used with servo brakes. The more common types available follow.

Basic Cable **Figure 51–12** shows a typical automatic adjusting system. Adjusters, whether cable, crank, or lever, are installed on one shoe and operated whenever the shoe moves away from its anchor. The upper link, or cable eye, is attached to the anchor. As the shoe moves, the cable pulls over a guide mounted on the shoe web (the crank or lever pivots on the shoe web) and operates a lever (pawl), which is attached to the shoe so it engages a star wheel tooth. The pawl is located on the outer side of the star wheel and, on different styles, slightly above or below the wheel centerline so it serves as a ratchet lock, which prevents the adjustment from backing off. However, whenever lining wears enough to permit sufficient shoe movement, brake application pulls the pawl high enough to engage the next tooth. As the brake is released, the adjuster spring returns the pawl, thus advancing the star wheel one notch.

On most vehicles, the adjuster system is installed on the secondary shoe and operates when the brakes are applied as the vehicle is backing up. On a few models, it is located on the primary shoe and operates when the brakes are applied as the vehicle is moving forward. Left-hand and right-hand threaded star wheels are used on opposite sides of the car, so parts should be kept separated. If the wrong star wheel thread is installed, the system does not adjust at all or will unadjust with every brake application.

Another system uses a cable and pawl, with the left brake having right-hand threads and the right brake, left-hand threads. The first cable guide is usually retained on the shoe web by the secondary shoe return spring, and the lever-pawl engages a hole in the shoe web. The adjuster operates in either direction of vehicle movement.

Cable with Overtravel Spring **Figure 51–13** shows a system with an upstroke pawl advance. The left brake has left-hand threads, and the right brake has right-hand threads. The lever (pawl) is installed on a web pin with an additional pawl return mousetrap spring. The cable is hooked to the lever (pawl) by means of an overtravel spring installed in the cable hook. The overtravel spring dampens movements and prevents unnecessary adjustment should sudden hard braking cause excessive drum deflection and shoe movement.

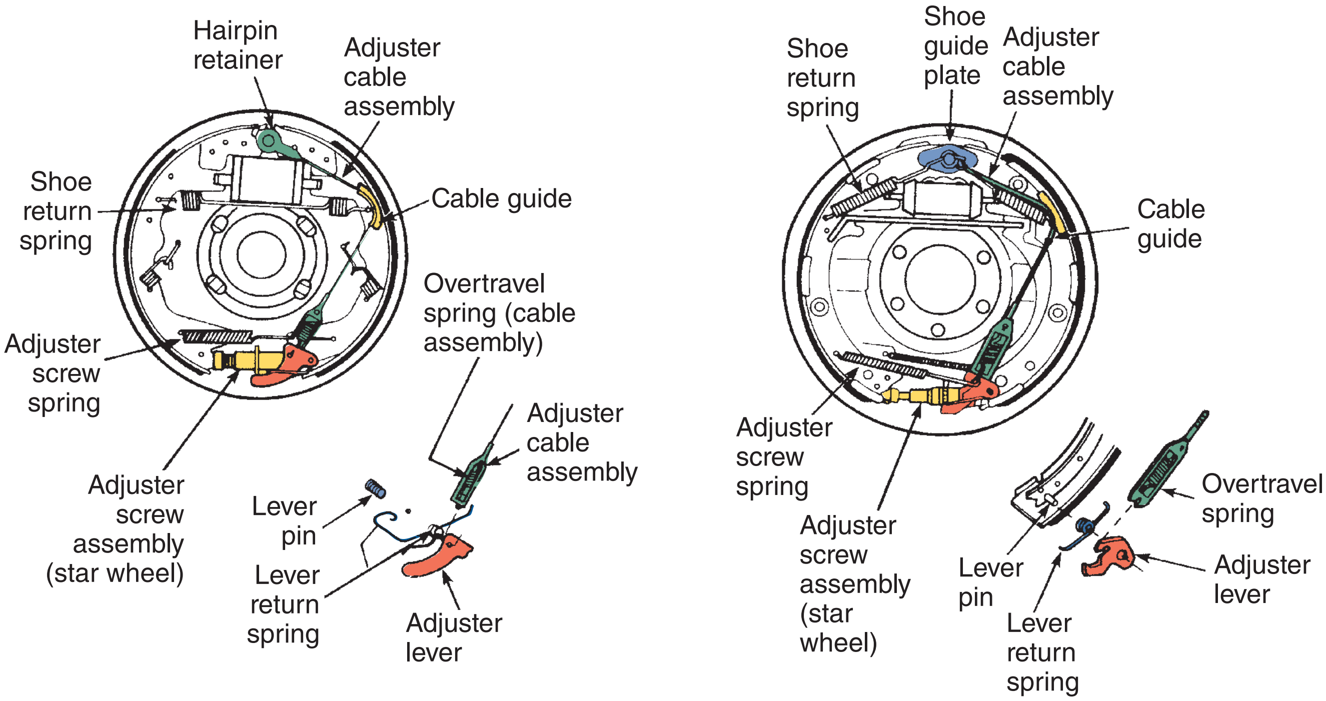

FIGURE 51–13 Cable automatic adjustment with overtravel springs.

Lever with Override The system illustrated in **Figure 51–14** uses a downstroke pawl advance. The left brake has right-hand threads, and the right brake has left-hand threads.

The lever (pawl) is mounted on a shoe holddown, pivoting on a cup sleeve. It has a separate lever-pawl return spring located between the lever and the shoe table. A pivot lever and an override spring assembled to the upper end of the main lever dampen movement, preventing unnecessary adjustment in the event of excessive drum deflection.

SHOP TALK It is important for the technician to remember that on nonservo drum systems the forward shoe is called the leading shoe and the rear one is known as the trailing shoe (when the vehicle is moving in the forward direction). On duo-servo designs, the forward shoe is the primary, and the rear is the secondary.

engages the pawl. A separate pawl return spring is located between the pawl and the shoe.

Nonservo Drum Brakes

The **nonservo drum brake** (or as it is better known today as the *leading-trailing* shoe drum brake) is often used on small cars. The basic difference between this type and the duo-servo brake is that both brake shoes are held against a fixed anchor at the bottom by a retaining spring **(Figure 51–16)**. Nonservo brakes have no servo action.

On a forward brake application, the forward (leading) shoe friction forces are developed by wheel cylinder fluid pressure forcing the lining into contact with the rotating brake drum. The shoe's friction forces work against the anchor pin at the bottom of the shoe. The trailing shoe is also actuated by wheel cylinder pressure but can only support a friction force equal to the wheel cylinder piston forces. The trailing shoe anchor pin supports no friction load. The leading shoe in this brake is energized and does most of the braking in comparison to the nonenergized trailing shoe. In reverse braking, the leading and trailing brake shoes switch functions.

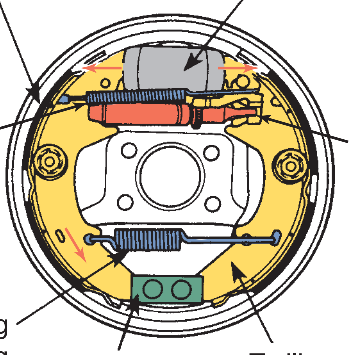

FIGURE 51–16 A typical nonservo drum brake.

Automatically Adjusted Nonservo Brakes

While some standard automatic adjusters similar to the one already discussed are employed on small cars, some of the automatic adjuster mechanisms are unique and varied, using expanding struts between the shoes, or special ratchet adjusting mechanisms. Among the more common of these designs are automatic cam, ratchet automatic, and semiautomatic adjusters.

Automatic Cam Adjusters This rear nonservo drum brake is for use with front disc brakes and has one forward acting (leading) and one reverse acting (trailing) shoe. Shoes rest against the wheel cylinder pistons at the top and are held against the anchor plate by a shoe-to-shoe pull-back spring. The anchor plate and retaining plate are riveted to the backing plate. Adjustment of the brake shoes takes place automatically as needed when the brakes are applied. The automatic cam adjusters are attached to each shoe by a pin through a slot in the shoe webbing. As the shoes move outward during application, the pin in the slot moves the cam adjuster, rotating it outward. Shoes always return enough to provide proper clearance because the pin diameter is smaller than the width of the slot.

Ratchet Automatic Adjuster These brakes are a leading-trailing shoe design with a ratchet self-adjusting mechanism. The shoes are held to the backing plate by spring and pin holddowns, and are held against the anchors at the top by a shoe-to-shoe spring. At the bottom, the shoe webs are held against the wheel cylinder piston ends by a return spring **(Figure 51–17)**.

The self-adjusting mechanism consists of a spacer strut and a pair of toothed ratchets attached to the secondary brake shoe. The parking brake actuating lever is pivoted on the spacer strut.

The self-adjusting mechanism automatically senses the correct lining-to-drum clearance. As the linings wear, the clearance is adjusted by increasing the effective length of the spacer strut. This strut has projections to engage the inner edge of the secondary shoe via the hand brake lever and the inner edge of the large ratchet on the secondary shoe. As wear on the linings increases, the movement of the shoes to bring them in contact with the drums becomes greater than the gap. The spacer strut, bearing on the

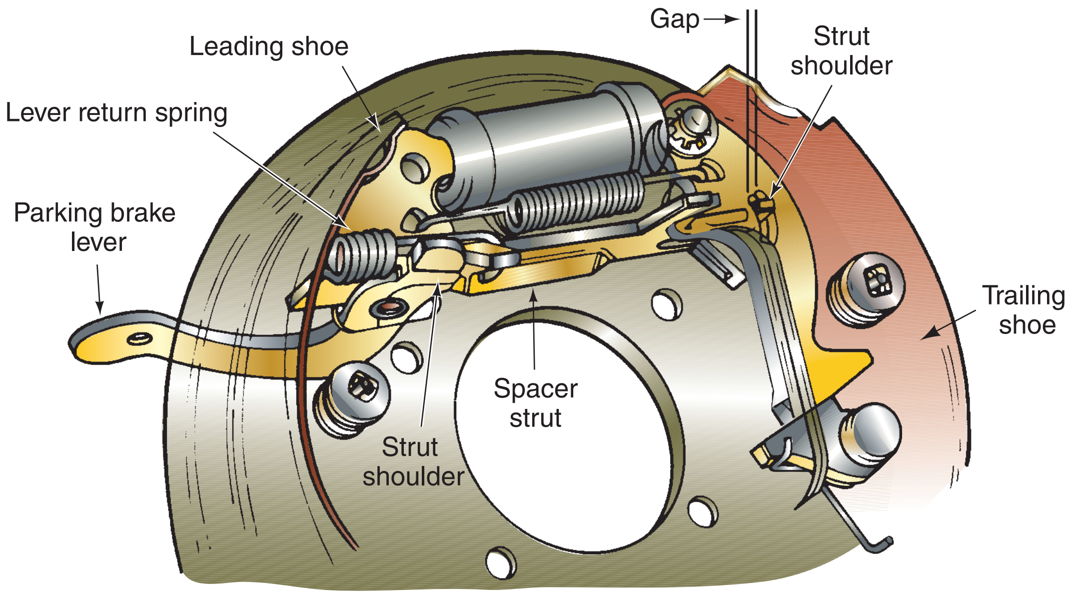

FIGURE 51–17 The ratchet-type self-adjuster for leading-trailing brakes is operated by the parking brake lever.

shoe web, is moved together with the primary shoe to close the gap. Further movement causes the large ratchet behind the secondary shoe to rotate inward against the spring-loaded small ratchet, and the serrations on the mating edges maintain this new setting until further wear on the shoe results in another adjustment. On releasing brake pedal pressure, the return springs cause the shoes to move into contact with the shoulders of the spacer strut/hand brake actuating lever. This restores the clearance between the linings and the drum proportionate to the gap.

Inspection and Service

The first rule of quality brake service is to perform a complete job. For example, perform an inspection of the entire brake system, not just the front or rear brakes. Also, if new linings are installed without regard to the condition of the hydraulic system, the presence of a leaking wheel cylinder quickly ruins the new linings. Braking power and safety are also compromised.

Problems such as spongy pedal, excessive pedal travel, pedal pulsation, poor braking ability, brake drag, lock, or pulling to one side, and braking noises can be caused by trouble in the hydraulic system or the mechanical components of the brake assembly. To aid in doing a complete inspection and diagnosis, a form like the one shown in **Figure 51–18** is very helpful. Working with such a form helps the technician avoid missing any brake test and components that may cause problems.

Brake Noise

All customer complaints related to brake performance must be carefully considered. The number one customer complaint is brake noise. Noise is often the first indication of wear or problems within the braking system, particularly in the mechanical components. Rattles, clicking, grinding, and hammering from the wheels when the brake is in the unapplied position should be carefully investigated. Be sure the noise is not caused by the bearings or various suspension parts. If the noise is coming from the brake assembly, it is most likely caused by worn, damaged, or missing brake hardware, or the poor fastening or mounting of brake components. Grinding noises usually occur when a stone or other object becomes trapped between the lining material and the rotor or drum.

When the brakes are applied, a clicking noise usually indicates play or hardware failure in the attachment of the pad or shoe. On recent systems, the noise could be caused by the lining tracking cutting tool marks on the rotor or drum. A nondirectional finish on rotors eliminates this and so does a less pointed tip on the cutting tool used to refinish drums.

Grinding noises on application can mean metal-to-metal contact, either from badly worn pads or shoes, or from a serious misalignment of the caliper, rotor, wheel cylinder, or backing plate. Wheel cylinders and calipers that are frozen due to internal corrosion can also cause grinding or squealing noises.

Other noise problems and their solutions are covered later in this chapter.

Road Testing Brakes

Road testing allows the brake technician to evaluate brake performance under actual driving conditions. Whenever practical, perform the road test before beginning any work on the brake system. In every case, road test the vehicle after any brake work to make sure the brake system is working safely and properly.

> **Warning!** Before test driving any car, first check the fluid level in the master cylinder. Depress the brake pedal to be sure there is adequate pedal reserve. Make a series of low-speed stops to be sure the brakes are safe for road testing. Always make a preliminary inspection of the brake system in the shop before taking the vehicle on the road.

Brakes should be road tested on a dry, clean, reasonably smooth, and level roadway. A true test of brake performance cannot be made if the roadway is wet, greasy, or covered with loose dirt. Testing is also adversely affected if the roadway is crowned so as to throw the weight of the vehicle toward the wheels on one side, or if the roadway is so rough that wheels tend to bounce.

Test brakes at different speeds with both light and heavy pedal pressure. Avoid locking the wheels and sliding the tires on the roadway. There are external conditions that affect brake road-test performance. Tires having unequal contact and grip on the road cause unequal braking. Tires must be equally inflated and the tread pattern of right and left tires must be approximately equal. When the vehicle has unequal loading, the most heavily loaded wheels require more braking power than others and a heavily loaded vehicle requires more braking effort. Misalignment of the front end may cause the brakes to pull to one side. Also, a loose front-wheel bearing could permit the drum to tilt and have spotty contact with brake shoe linings, causing pulsations when the brakes are applied. Faulty shock absorbers that do not prevent the car from bouncing on quick stops can give the erroneous impression that the brakes are too severe.

Drum Brake Inspection

Place the vehicle in neutral, release the parking brake, and raise the vehicle on the hoist. Once the wheels are removed, mark the wheel-to-drum and drum-to-axle positions so the components can be correctly reassembled.

Drum Removal

Drum removal procedures are different for fixed and floating drums. In all cases, however, you may need to manually retract the self-adjusters **(Figure 51–19)** to have enough shoe-to-drum clearance to remove the drum. Wear on the friction surface of the drum creates

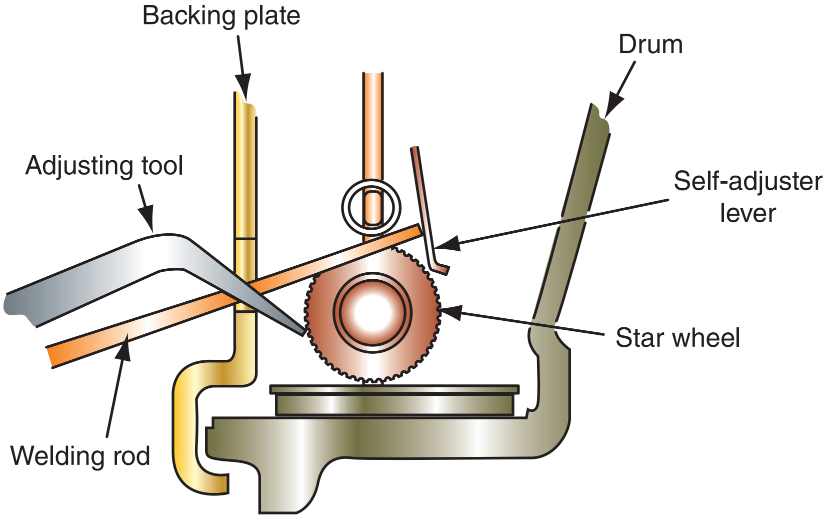

FIGURE 51–19 Use a heavy piece of wire to move the adjusting lever away from the star wheel, then rotate the star wheel to move the brake shoe away from the drum before removing the drum.

a ridge at the edge of the drum's rim. As the self-adjusters move the shoes outward to take up clearance, the shoe diameter becomes larger than the ridge diameter. If the adjuster is not retracted, the drum's ridge may jam on the shoes and prevent drum removal. Trying to force the drum over the shoes may damage brake parts. To retract the shoes, reach through the adjusting slot with a thin screwdriver (or similar tool) and carefully push the self-adjusting lever away from the star wheel a maximum of $^{1}/_{16}$ inch. While holding the lever back, insert a brake adjusting tool into the slot and turn the star wheel in the proper direction until the brake drum can be removed. On vehicles that have the adjusting slot in the drum rather than in the backing plate, reach through the slot with a thin wire hook and pull the adjuster lever away from the star wheel.

Before you remove a drum, mark it "L" or "R" for left or right so that it gets reinstalled on the same side of the vehicle from which it was removed.

Warning! Do not step on the brake pedal while a brake drum is off. This will cause the pistons in the wheel cylinder to overextend or pop apart.

Brake drums that are made as a one-piece unit with the wheel hub were common on FWD cars and on the front wheels of older vehicles with four-wheel drum brakes. The hub contains the wheel bearings and is held onto the spindle by a single large nut. This nut also is used to adjust the wheel bearings. To remove this type of drum, remove the dust cap from the center of the hub. Then remove the cotter pin from the castellated nut or nut lock on the spindle. Next, remove the spindle nut and washer. Pull the drum outward to slide it off the spindle.

On older 4WD trucks, the rear drums are held in place by the rear axle and wheel bearings. First, remove the bolts securing the axle to the hub and then remove the axle. In most cases, a special socket is required to remove the retaining nut and remove the bearings. Once the bearings are removed, the drum can be removed.

Floating drums do not have a built-in hub. In most cases, the drums are held in place by studs on the axle flange and the wheel and lug nuts. On many floating drums, push nuts or speed nuts are used during vehicle assembly to hold the drum onto two or three studs. Typically the push nuts do not need to be reinstalled after service. However, on some vehicles, the push nuts are used to hold the drum squarely against the axle or hub flange.

FIGURE 51–20 Pull the drum away from the axle flange or hub, being careful not to drop it.

Floating drums are pulled off the hub or axle flange **(Figure 51–20)**. If the brake drum is rusted or corroded to the axle flange and cannot be removed, lightly tap the axle flange to the drum mounting surface with a ball-peen hammer. Many drums have threaded holes in the face to help remove the drum. Thread two bolts into the holes **(Figure 51–21)** and tighten evenly. The bolts will thread against the axle flange and push the drum off the hub. Penetrating oil may help in loosening a stuck drum. If the drum is

FIGURE 51–21 Threaded holes allow for easier drum removal.

stuck to its flange, use a large scribe or center punch to score around the joint at the drum and flange and break the surface tension. Remember that if the drum is worn, the brake shoe adjustment has to be backed off for the drums to clear the brake shoes. Do not force the drum or distort it. Do not pry against the drum using the backing plate, this will damage or possibly bend the backing plate. Once loose, do not allow the drum to drop.

Once the drum is removed, inspect the brake assembly for signs of fluid leakage from the wheel cylinder and, on RWD vehicles, from the rear axle seals. Faulty axle seals, shown in **(Figure 51–22)**, allow differential lubricant to leak out and contaminate the rear brake components. When this occurs, the shoes must be replaced because the fluid cannot be cleaned from the lining material.

Fixed Drums After the drum is removed, inspect the grease in the hub and on the bearings. If the grease is dirty or dried out and hard, it is a clue to possible bearing damage. Also inspect the rear axle gaskets and wheel seals for leaks. Replace worn components as needed. Set the drum and all bearing parts aside for cleaning and close inspection. If the grease seems to be in good condition, place the drum on a bench with the open side down. Cover the outer bearing opening with a shop cloth to keep dirt out.

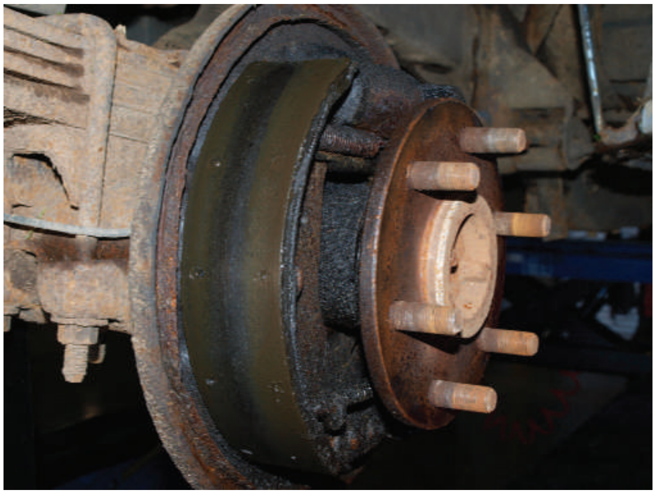

FIGURE 51–22 Faulty axle seals allow axle fluid to leak and contaminate the brake linings.

FIGURE 51–23 Before disassembling the brakes, use an OSHA-approved washer to make sure all asbestos dust is removed from the parts.

> **Caution!** When servicing wheel brake parts, do not create dust by cleaning with a dry brush or with compressed air. Asbestos fibers can become airborne if dust is created during servicing. Breathing dust containing asbestos fibers can cause serious bodily harm. To clean away asbestos from brake surfaces, use an OSHA-approved washer **(Figure 51–23)**. Follow the manufacturer's instructions when using the washer.

Drum Inspection

One of the most important parts that need to be inspected is the brake drum **(Figure 51–24)**. Thoroughly clean the drums with a water-dampened cloth or a water-based solution. If the drums have been exposed to leaking oil or grease, thoroughly clean them with a non-oil base solvent after washing to remove dust and dirt. It is important to determine the source of the oil or grease leak and correct the problem before reinstalling the drums.

Brake drums act as a heat sink. They absorb heat and dissipate it into the air. As drums wear from normal use or are machined, their cooling surface area is reduced and their operating temperatures increase. Their structural strength is also reduced. This leads to distortion, which causes some of the drum conditions shown in **(Figure 51–25)**.

Also take a look at the brake shoes while they are still mounted. Their condition can often reveal defects in the drums. If the linings on one wheel are worn more than the others, it might indicate a rough drum. Uneven wear from side to side on any one set of shoes can be caused by a tapered drum. If some linings are worn badly at the toe or heel, it might indicate an out-of-round drum.

FIGURE 51–24 Carefully check the inside surface of the brake drum.

Scored Drum Surface The most common cause of this condition is buildup of brake dust and dirt between the brake lining and drum. A glazed brake lining, hardened by high heat or in some cases by very hard inferior grade brake lining, can also groove the drum surface. Excessive lining wear that exposes the rivet head or shoe steel will score the drum surface. If the grooves are not too deep, the drum can be turned.

Bell-Mouthed Drum This distortion is due to extreme heat and braking pressure. It occurs mostly on wide drums and is caused by poor support at the outside of the drum. Full drum-to-lining contact cannot be achieved and fading can be expected. Drums must be turned.

Concave Drum This is an excessive wear pattern in the center area of the drum brake surface. Extreme braking pressure can distort the shoe platform so braking pressure is concentrated at the center of the drum.

Convex Drum This wear pattern is greater at the closed end of the drum. It is the result of excessive heat or an oversized drum, which allows the open end of the drum to distort.

Hard Spots on the Drum This condition in the cast-iron surface, sometimes called chisel spots or islands of steel, results from a change in metallurgy caused by braking heat. Chatter, pulling, rapid wear, hard pedal, and noise can occur. These spots can be removed by grinding. However, only the raised surfaces are removed, and they can reappear when heat is applied. If this condition reappears, the drum must be replaced.

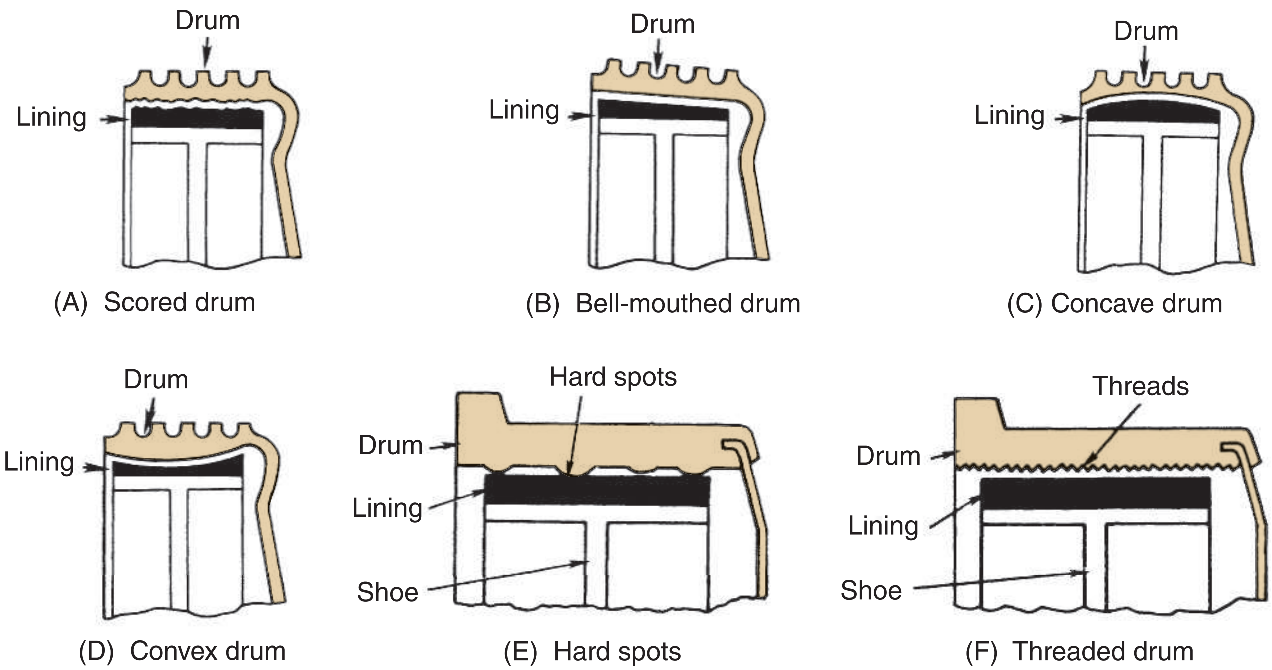

FIGURE 51–25 Drum wear conditions.

Threaded Drum Surface An extremely sharp or chipped tool bit or a lathe that turns too fast can result in a threaded drum surface. This condition can cause a snapping sound during brake application as the shoes ride outward on the thread, then snap back. To avoid this, recondition drums using a rounded tool and proper lathe speed. Check the edge of the drum surface around the mounting flange side for tool marks indicating a previous machining. If the drum has been machined, it might have worn too thin for use. Check the diameter.

Heat Checks **Heat checks** are visible, unlike hard spots that do not appear until the machining of the drum **(Figure 51–26)**. Extreme operating temperatures are the major cause. The drum might also show a bluish/gold tint, which is a sign of high temperatures. Hardened carbide lathe bits or special grinding attachments are available through lathe manufacturers to service these conditions. Excessive damage by heat checks or hard spots requires drum replacement.

Cracked Drum Cracks in the cast-iron drum are caused by excessive stress. They can be anywhere but usually are in the vicinity of the bolt circle or at the outside of the flange. Fine cracks in the drums are often hard to see and, unfortunately, often do not show up until after machining. Nevertheless, should any cracks appear, no matter how small, the drum must be replaced.

Out-of-Round Drums Drums with eccentric distortion might appear fine to the eye but can cause pulling, grabbing, and pedal vibration or pulsation. An out-of-round or egg-shaped condition is often caused by heating and cooling during normal brake operation. Out-of-round drums can be detected before the drum is removed by adjusting the brake to a light drag and feeling the rotation of the drum by hand. After removing the drum, gauge it to determine the amount of eccentric distortion. Drums with this defect should be machined or replaced.

FIGURE 51-27 Measuring the inside diameter with a drum micrometer.

Drum Measurements

Measure every drum with a drum micrometer **(Figure 51–27)**, even if the drum passed a visual inspection, to make sure that it is within the safe oversize limits. If the drum is within safe limits, even though the surface appears smooth, it should be turned to ensure a true drum surface and to remove any possible contamination in the surface from previous brake linings, road dust, and so forth. Remember that if too much metal is removed from a drum, unsafe conditions can result.

Take measurements at the open and closed edges of the friction surface and at right angles to each other. Drums with taper or out-of-roundness exceeding 0.006 inch (0.152 mm) are unfit for service and should be turned or replaced. If the maximum diameter reading (measured from the bottom of any grooves that might be present) exceeds the new drum diameter by more than 0.060 inch (1.5 mm), the drum cannot be reworked. If the drums are smooth and true but exceed the new diameter by 0.090 inch (2.2 mm) or more, they must be replaced.

Drum Refinishing

Brake drums can be refinished by either turning or grinding on a brake lathe **(Figure 51–28)**.

Only enough metal should be removed to obtain a true, smooth friction surface. When one drum must be machined to remove defects, the other drum on the same axle set must also be machined in the same manner and to the same diameter (±0.010 inches) so braking is equal.

FIGURE 51–28 Brake drums can be resurfaced by grinding or turning them on a brake lathe.

USING SERVICE INFORMATION

Service information lists the standard brake drum inside diameter along with the discard dimension. They also state the standard and minimum lining thickness. Manual illustrations should be used to accurately identify all components plus the disassemble/reassembly procedure. Tightening specifications for backing plate nuts and other components should always be followed.

SHOP TALK

Keep the adjusting screws and automatic adjuster parts for left and right brakes separate. These parts usually are different. For example, on some automatic adjusters, the adjusting screws on the right brakes have left-hand threads and the adjusting screws on the left brakes have right-hand threads.

Brake drums are stamped with a discard dimension **(Figure 51–29)**. This is the allowable wear dimension and not the allowable machining dimension. There must be 0.030 inch (0.762 mm) left for wear after turning the drums. Some states have laws about measuring the limits of a brake drum.

Machining or grinding brake drums increases the inside diameter of the drum and changes the lining-to-drum fit. When remachining a drum, follow the equipment instructions for the specific tool you are using.

FIGURE 51–29 The drum's discard diameter is stamped on the drum.

Cleaning Newly Refaced Drums

The friction surface of a newly refaced drum contains millions of tiny metal particles. These particles not only remain free on the surface, they also lodge themselves in the open pores of the newly machined surface. If the metal particles are allowed to remain in the drum, they become embedded in the brake lining. Once the brake lining gets contaminated in this manner, it acts as a fine grinding stone and scores the drum.

SHOP TALK

Mark the shoe positions if shoes and linings are to be reused. When disassembling an unfamiliar brake assembly, work on one wheel at a time and use the other wheel as a reference.

PROCEDURE

Mechanical Component Service of Duo-Servo Drum Brakes

STEP 1 Clean the brake dust from the brake assembly using the appropriate cleaning equipment.

STEP 2 If required, install wheel cylinder clamps on the wheel cylinders to prevent fluid leakage or air from getting into the system while the shoes are removed. Some brakes have wheel cylinder stops; therefore, wheel cylinder clamps are not required. Regardless of whether the clamps are needed, do not press down on the brake pedal after shoe return springs have been removed. To prevent this, block up the brake pedal so it cannot be depressed.

STEP 3 Remove the brake shoe return springs. Use a brake spring removal and installation tool to unhook the springs from the anchor pin or anchor plate **(Figure 51–30)**.

STEP 4 Remove the shoe retaining or holddown cups and springs. Special tools are available **(Figure 51–31)**, but the holddown springs can be removed by using pliers to compress the spring and rotating the cup with relation to the pin.

STEP 5 Self-adjuster parts can now be removed. Lift off the actuating link, lever and pivot assembly, sleeve (through lever), and return spring. No advantage is gained by disassembling the lever and pivot assembly unless one of the parts is damaged.

STEP 6 Spread the shoes slightly to free the parking brake strut and remove the strut with its spring. Disconnect the parking brake lever from the secondary shoe. It can be attached with a retaining clip, bolt, or simply hooked into the shoe.

STEP 7 Slip the anchor plate off the pin. No advantage is gained by removing the plate if it is bolted on or riveted. Spread the anchor ends of the shoes and disengage them from the wheel cylinder links, if used. Remove the shoes connected at the bottom by the adjusting screw and spring, as an assembly.

STEP 9 Overlap the anchor end of the shoes to relieve spring tension. Unhook the adjusting screw spring and remove the adjusting screw assembly.

PROCEDURE

Disassembling Nonservo or Leading-Trailing Brakes

STEP 1 Install the wheel cylinder clamp. Then unhook the adjuster spring from the parking brake strut and reverse shoe.

STEP 2 Unhook the upper shoe-to-shoe spring from the shoes and unhook the antinoise spring from the spring bracket.

STEP 3 Remove the parking brake strut and disengage the shoe webs from the flat, clamp shoe holddown clips.

STEP 4 Unhook the lower shoe-to-shoe spring and remove the forward shoe. Disconnect the parking brake cable, then remove the reserve shoe.

STEP 5 Remove the shoe holddown clips from the backing plate.

STEP 6 Press off the C-shaped retainers from the pins and remove the parking brake lever, automatic adjuster lever, and adjuster latch.

STEP 7 Remove the parking brake lever.

PROCEDURE

Cleaning and Inspecting Brake Parts

STEP 1 Clean the backing plates, struts, levers, and other metal parts to be reused using a water-dampened cloth or a water-based solution. Equipment is commercially available to perform washing functions of brake parts. Wet cleaning methods must be used to prevent asbestos fibers from becoming airborne.

STEP 2 Carefully examine the raised shoe support pads on the backing plate to make sure they are free from corrosion or other surface defects that might prevent the shoes from sliding freely **(Figure 51–32)**. Use fine emery cloth to remove surface defects, if necessary. Clean them thoroughly.

STEP 3 Check to make sure that the backing plates are not cracked or bent. If so, they must be replaced. Make sure backing plate bolts and bolted-on anchor pins are torqued to specifications.

STEP 4 If replacement of the wheel cylinder is needed, it should be done at this time. To determine wheel cylinder condition, carefully inspect the boots. If they are cut, torn, heat-cracked, or show evidence of leakage, the wheel cylinders should be replaced. If more than a drop of fluid spills out, leakage is excessive and indicates that replacement is necessary.

STEP 5 Disassemble the adjusting screw assembly **(Figure 51–33)** and clean the parts in a suitable solvent. Make sure the adjusting screw threads into the pivot nut over its complete length without sticking or binding. Check that none of the adjusting screw teeth are damaged. Lubricate the adjusting screw threads with brake lubricant.

STEP 6 Examine the shoe anchor, support plate, and small parts for signs of looseness, wear, or damage that could cause faulty shoe alignment. Check springs for spread or collapsed coils, twisted or nicked shanks, and severe discoloration **(Figure 51–34)**. Operate star wheel automatic adjusters by prying the shoe lightly away from its anchor or by pulling the cable to make sure the adjuster advances easily, one notch at a time. Adjuster cables tend to stretch, and star wheels and pawls become blunted after a long period of use. For rear-axle parking brakes, pull on the cable and shoe linkage to make sure no binding condition is present that could cause the shoes to drag when the parking brake is released.

FIGURE 51-32 Carefully examine the raised shoe support pads on the backing plate.

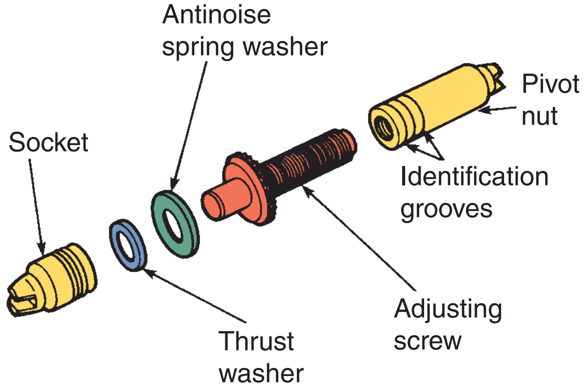

FIGURE 51-33 An exploded view of a brake adjuster assembly.

These metal particles must be removed by washing or cleaning the drum. Do not blow out the drum with air pressure. Either of the following methods is recommended to clean a newly refaced brake drum.

The first method involves washing the brake drum thoroughly with hot soapy water and wiping with a lint-free rag. Then use the air pressure to thoroughly dry it. If the front hub and drums are being cleaned, be very careful to avoid contaminating the wheel bearing grease. Or, completely remove all the old grease, then regrease and repack the wheel bearing after the drum has been cleaned and dried. The wheel bearings and the grease seals must be removed from the drum before cleaning.

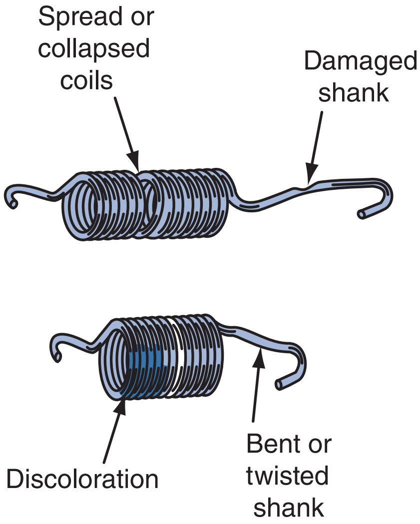

FIGURE 51-34 All springs should be checked for distortion and damage.

The second method involves wiping the inside of the brake drum (especially the newly machined surface) with a lint-free white cloth dipped in one of the many available brake cleaning solvents that do not leave a residue. This operation should be repeated until dirt is no longer apparent on the wiping cloth. Allow the drum to dry before reinstalling it on the vehicle.

Both of these procedures are also good for cleaning disc brake rotors.

Brake Shoes and Linings

Lining materials influence braking operation. The use of a lining with a friction value that is too high can result in a severe grabbing condition. A friction value that is too low can make stopping difficult because of a hard pedal.

Overheating a lining accelerates wear and can result in dangerous lining heat fade—a friction-reducing condition that hardens the pedal and lengthens the stopping distance. Continual overheating eventually pushes the lining beyond the point of recovery into a permanent fade condition. In addition to fade, overheating can cause squeal.

Overheating is indicated by a lining that is charred or has a glass-hard glazed surface, or if severe, random cracking of the surface is present.

Inspect the linings for uneven wear, embedded foreign material, loose rivets, and to see if they are oil soaked. If linings are oil soaked, replace them.

Caution! Automotive friction materials may contain substantial amounts of asbestos. Studies indicate that exposure to excessive amounts of asbestos dust can be a potential health hazard. It is important that anyone handling brake linings understands this and takes the necessary precautions to avoid injury.

If linings at any wheel show a spotty wear pattern or an uneven contact with the brake drum, it is an indication that the linings are not centered in the drums. Linings should be circle ground to provide better contact with the drum.

Brake Shoe Replacement

Brake linings that are worn to within $^1/_{32}$ inch (0.79 mm) of a rivet head or that have been contaminated with brake fluid, grease, or oil must be replaced **(Figure 51–35)**. Failure to replace worn linings results in a scored drum. When it is necessary to replace brake shoes, they must also be replaced on the wheel on the opposite side of the vehicle. Inspect brake shoes for distortion, cracks, or looseness. If these conditions exist, the shoe must be discarded.

Do not let brake fluid, oil, or grease touch the brake lining.

Selecting Replacement Linings

Identification codes, called the automotive friction material edge codes, are printed on the edges of drum brake linings **(Figure 51–36)** and disc brake pads. The letters and numbers identify the manufacturer of the

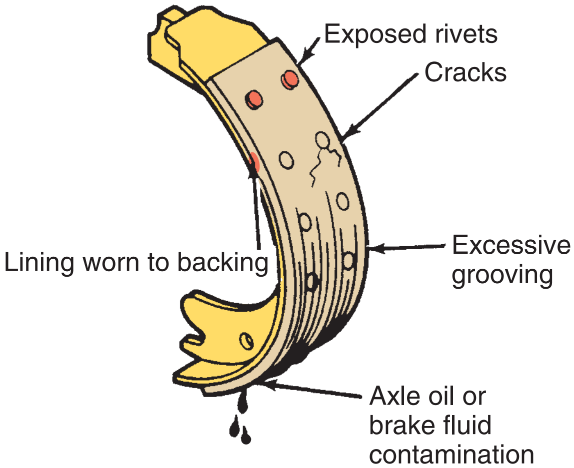

FIGURE 51–35 Potential brake shoe problems.

FIGURE 51–36 Identification codes, called the automotive friction material edge codes, are printed on the edges of drum brake linings.

lining material and the material used, and the last two letters identify the cold and hot coefficients of friction (COF).

These codes do not address lining quality or its hardness. From a service standpoint, the hot and cold COF codes are the most important and are coded as follows:

C = not over 0.15

D = over 0.15 but not over 0.25

E = over 0.25 but not over 0.35

F = over 0.35 but not over 0.45

G = over 0.45 but not over 0.55

H = over 0.55

It is also important to use the recommended friction material when replacing brake shoes. The incorrect type of friction material can affect the stopping characteristics of the car.

Hard and *soft* are terms applied to linings within a general category of material. Thus, any particular organic lining may be considered as a hard or a soft organic material. Overall, organic linings are considered softer than semimetallic linings, and semimetallic linings are considered softer than fully metallic linings. A hard lining usually has a low COF but resists fade better and lasts longer than a soft lining. A soft lining has a higher COF but fades sooner and wears faster than a hard lining. A soft lining is less abrasive on drum surfaces and operates more quietly than a hard lining. It also is common to use linings with a lower COF on the rear brakes than on the front to minimize rear brake lockup.

SHOP TALK

On duo-servo shoe designs, the forward shoe is the primary and the rear, the secondary. The secondary shoe lining is longer.

Sizing New Linings

Modern brake shoes are usually supplied with what is known as cam, offset, contour, or eccentric shape, which is ground in at the factory. That is, the full thickness of the lining is only present at the heel and toe of the shoe, and is ground down slightly at the center. The diameter of the circle the shoes make is slightly smaller than that of the drum. This compensates for the minor tolerance variations of drums and brake mountings and promotes proper wearing-in of the linings to match the drum.

Lining Adjustment

New eccentric-ground linings tolerate a closer new lining clearance adjustment than concentric ground linings. With manual adjusters, the shoes should be expanded into the drums until the linings are at the point of drag but not dragging heavily against the drum. With star wheel automatic adjusters, a drum/shoe gauge **(Figure 51–37)** provides a convenient means of making the preliminary adjustment. This type of gauge, when set at actual drum diameter, automatically provides the working clearance of the shoes **(Figure 51–38)**. If new linings have been concentrically ground, the initial clearance adjustment must be backed off an amount that provides sufficient working clearance.

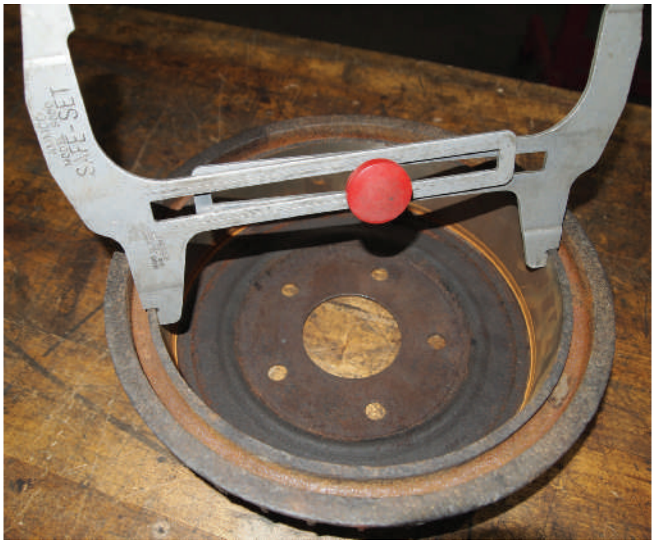

FIGURE 51–37 Using a brake shoe set gauge to match the diameter of the drum to the brake shoes so further shoe adjustment is limited.

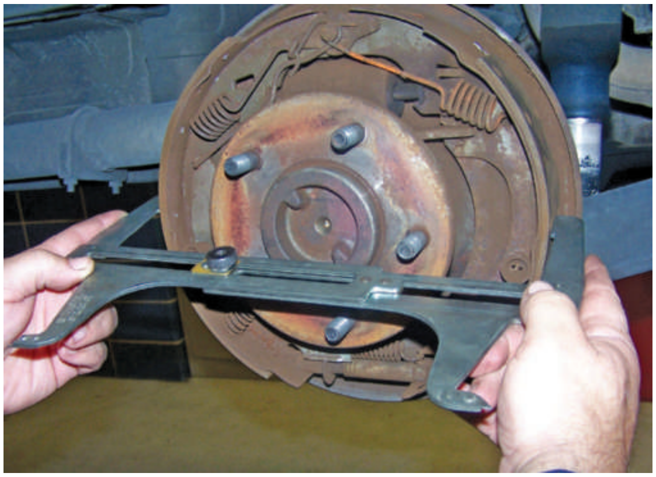

FIGURE 51–38 Using the other side of the brake gauge to set the brake shoes.

Drum Shoe and Brake Installation

Before installing the shoes, sand the inner edge of the shoe to smoothen any metal nicks and burrs that could interfere with the sliding on the support pads.

A support (backing) plate must be tight on its mount and not bent. Remove any burrs or grooves on the shoe support pads that could cause the shoes to bind or hang up.

Using an approved lubricant, lightly coat the support pads **(Figure 51–39)** and the threads of servo star wheel adjusters. On rear axle parking brakes, lubricate any point of potential binding in the linkage and the cable.

SHOP TALK

Some brake technicians check brake spring tension by the drop method. This method is not overly scientific and the results are not always correct. Drop the brake spring on a clean concrete floor. If it bounces with a chunky sound, it is good. If the bounced spring gives off a tinny sound, it is tired and should be replaced. Many technicians simply replace the springs as part of the brake service. This ensures the brake hardware will be in good condition.

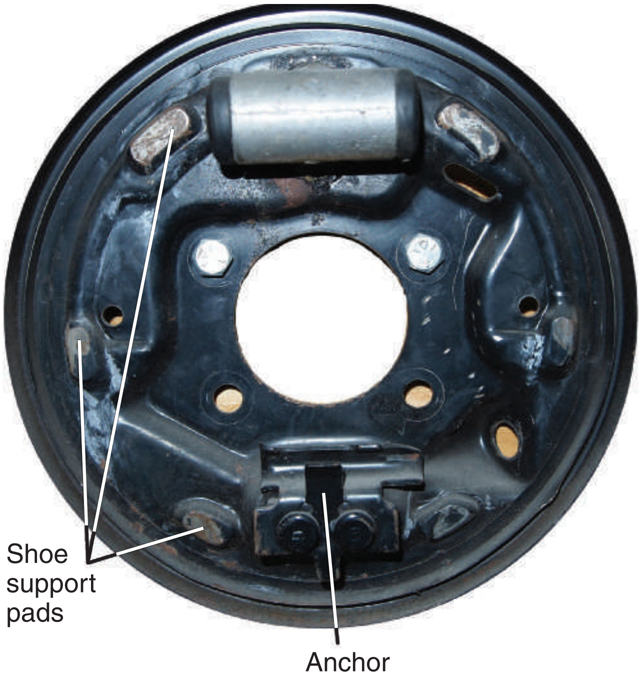

FIGURE 51-39 The areas or pads where the brake shoe will rub or contact the backing plate.

Prior to installing the new shoes, some technicians cover the linings with masking tape to prevent lubricant, dirt, and other contaminates from getting on the linings. Reassemble the brakes in the reverse order of disassembly. Make sure all parts are in their proper locations and that both brake shoes are properly positioned in both ends of the adjuster. Also, both brake shoes should correctly engage the wheel cylinder pushrods and parking brake links. They should be centered on the backing plate. Parking brake links and levers should be in place on the rear brakes. With all of the parts in place, try the fit of the brake drum over the new shoes. If not slightly snug, pull it off and turn the star wheel until a slight drag is felt when sliding on the drum. A brake preset gauge makes this job easy and final brake adjustment simple. Then install the brake drum and wheel/tire assemblies, and make the final brake adjustments as specified in individual instructions in the vehicle's service information. Torque the spindle and lug nuts to specifications.

Wheel Cylinder Inspection and Servicing

Wheel cylinders might need replacement when the brake shoes are replaced or when they begin to leak.

Inspecting and Replacing Wheel Cylinders

Wheel cylinder leaks reveal themselves in several ways: (1) fluid can be found when the dust boot is peeled back **(Figure 51–40)**; (2) the cylinder, linings, and backing plate, or the inside of a tire might be wet; or (3) there might be a drop in the level of fluid in the master cylinder reservoir.

Such leaks can cause the brakes to grab or fail and should be immediately corrected. Note the amount of fluid present when the dust boot is pulled back. A small amount of fluid seepage dampening the interior of the boot is normal. A dripping boot is not.

Warning! Hydraulic system parts should not be allowed to come in contact with oil or grease. They should not be handled with greasy hands. Even a trace of any petroleum-based product is sufficient to cause damage to the rubber parts.

Cylinder binding can be caused by rust deposits, swollen cups due to fluid contamination, or by a cup wedged into an excessive piston clearance. If the clearance between the pistons and the bore wall exceeds allowable values, a condition called heel drag might exist. It can result in rapid cup wear and can cause the piston to retract very slowly when the brakes are released.

Care must be taken when installing new or reconditioned wheel cylinders on cars equipped with

FIGURE 51-40 Pull back the wheel cylinder's dust boot to check for internal wheel cylinder leaks.

wheel cylinder piston stops. The rubber dust boots and the pistons must be squeezed into the cylinder before it is tightened to the backing plate. If this is not done, the pistons jam against the stops causing hydraulic fluid leaks and erratic brake performance.

Drum Parking Brakes

The parking brake keeps a vehicle from rolling while it is parked. It is important to remember that the parking brake is not part of the vehicle's hydraulic braking system. It works mechanically, using a lever assembly connected through a cable system to the rear drum service brakes.

Types of Parking Brake Systems

Parking brakes can be either hand or foot operated. In general, downsized cars and light trucks use hand-operated self-adjusting lever systems **(Figure 51–41)**. Full-size vehicles normally use a foot-operated parking brake pedal **(Figure 51–42A)**.

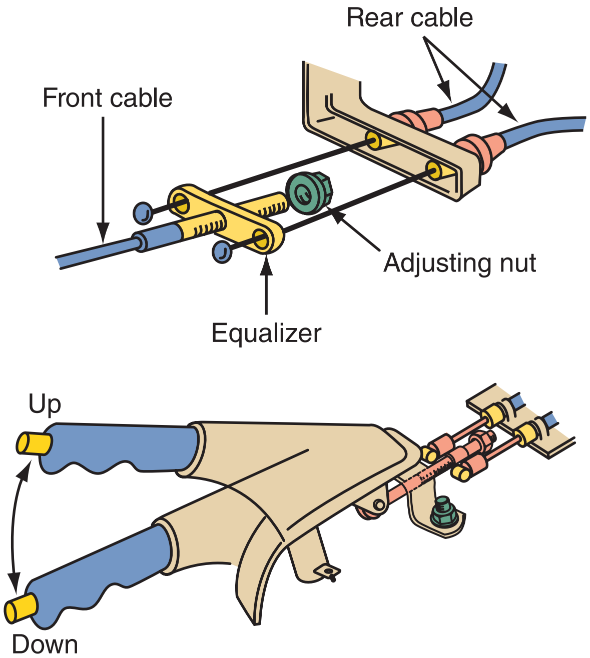

FIGURE 51–41 A typical setup for a center-mounted hand-operated parking brake.

PROCEDURE

Replacing a Wheel Cylinder

STEP 1 Because brake hoses are an important link in the hydraulic system, it is recommended that they be replaced when a new cylinder is to be installed or when the old cylinder is to be reconditioned. Remove the brake shoe assemblies from the backing plate before proceeding. The smallest amount of brake fluid contaminates the friction surface of the brake lining.

STEP 2 Use the appropriate tubing wrench and disconnect the hydraulic line where it enters the wheel cylinder. Care must be taken while removing this steel line. It might break or bend and be difficult to reinstall.

STEP 3 Remove the plates, shims, and bolts that hold the wheel cylinder to the backing plate. Some later design wheel cylinders are held to the backing plate with a retaining ring that can be removed with two small picks.

STEP 4 Remove the wheel cylinder from the backing plate and clean the area with a proper cleaning solvent.

STEP 5 Install the new wheel cylinder. Care must be taken when installing wheel cylinders on cars equipped with wheel cylinder piston stops. The rubber dust boots and pistons must be squeezed into the cylinder before it is tightened to the backing plate. If this is not done, the pistons will jam against the stops, causing fluid leaks and erratic brake performance.

STEP 6 Thread the brake line into the cylinder before attaching the wheel cylinder to the backing plate. Once the cylinder's mounting bolts are tightened to specifications, tighten the brake line. Then reassemble the brake unit and bleed the system.

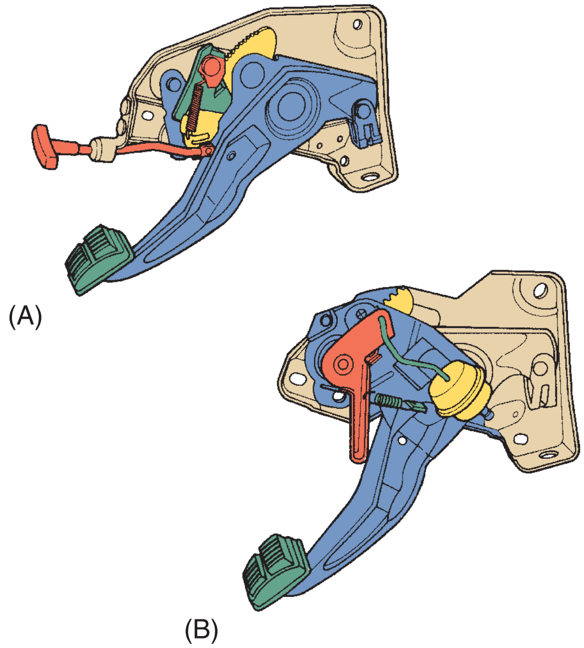

FIGURE 51–42 Typical pedal-operated parking brakes: (A) mechanical release and (B) vacuum release.

The pedal or lever assembly is designed to latch into an applied position and is released by pulling a brake release handle or pushing a release button.

On some vehicles, a vacuum power unit **(Figure 51–42B)** is connected by a rod to the upper end of the release lever. The vacuum motor is actuated to release the parking brake whenever the engine is running and the transmission is in forward driving gear. The lower end of the release lever extends down for alternate manual release in the event of vacuum power failure or for optional manual release at any time. Hoses connect the power unit and the engine manifold to a vacuum release valve on the steering column.

The starting point of a typical parking brake cable and lever system is the foot pedal or hand lever. This assembly is a variable ratio lever mechanism that converts input effort of the operator and pedal/lever travel into output force with less travel. Tensile force from the front cable is transmitted through the car's brake cable system to the rear brakes. This tension pulls the flexible steel cables attached to each of the rear brakes. It operates the internal lever and strut mechanism of each rear brake, expanding the brake shoes against the drum. Springs return the shoes to the unapplied position when the parking brake pedal is released and tensile forces in the cable system are relaxed.

An electronic switch, triggered when the brake pedal is applied, lights the brake indicator in the instrument panel when the ignition is turned on. The light goes out when either the pedal or control is released or the ignition is turned off.

The cable/lever routing system in a typical parking brake arrangement uses a three-lever setup to multiply the physical effort of the operator. First is the pedal assembly or hand grip. When moved, it multiplies the operator's effect and pulls the front cable. The front cable, in turn, pulls the equalizer lever.

The **equalizer lever** multiplies the effort of the pedal assembly, or hand grip, and pulls the rear cables. This pulling effort passes through an equalizer, which ensures equal pull on both rear cables. The equalizer functions by allowing the rear brake cables to slip slightly to balance out small differences in cable length or adjustment.

Figure 51–43 shows a typical parking brake system. When the parking brake pedal is applied, the cables and equalizer exert a balanced pull on the parking brake levers of both rear brakes. The levers and the parking brake struts move the shoes outward against the brake drums. The shoes are held in this position until the parking brake pedal is released.

The rear cable enters each rear brake through a conduit **(Figure 51–44)**. The cable end engages the

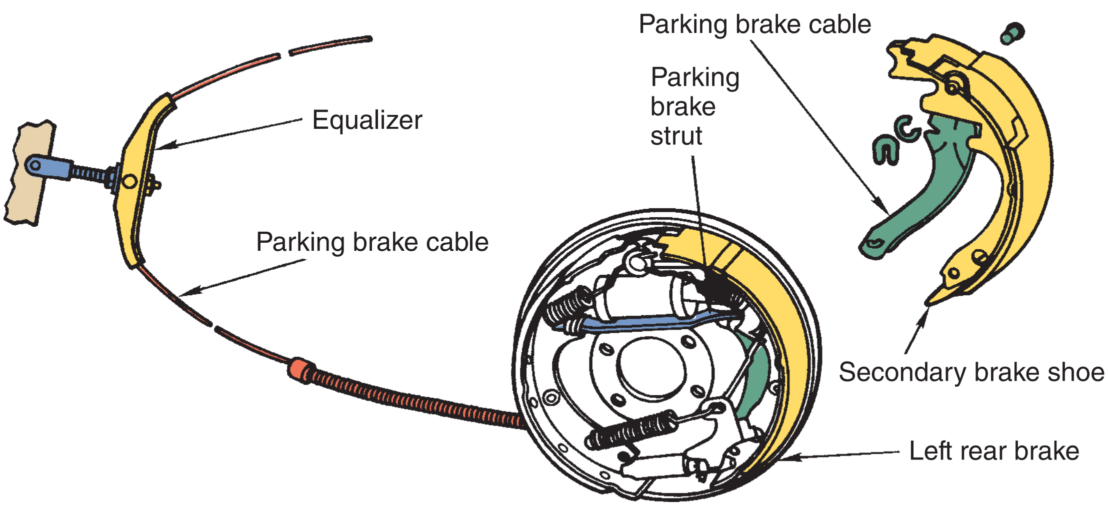

FIGURE 51–43 Parking brake components.

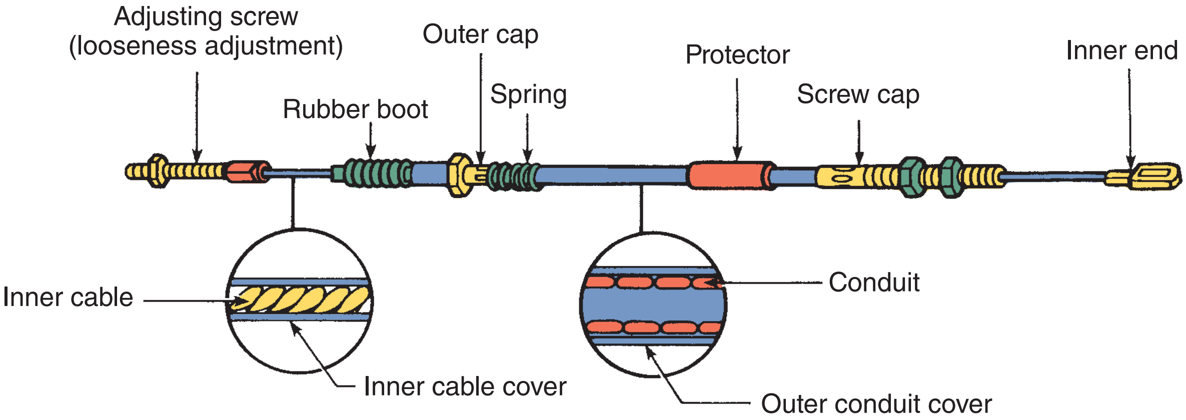

FIGURE 51-44 Rear cable and conduit details.

lower end of the parking brake lever. This lever is hinged to the web of the secondary shoe and linked with the primary shoe by means of a strut. The lever and strut expand both shoes away from the anchor and wheel cylinder and into contact with the drum as the cable and lever are drawn forward. The shoe return springs reposition the shoes when the cable is slacked.

To remove and replace the brake shoes, it might be necessary to relieve the parking brake cable tension by backing off the adjusting nuts at the equalizer.

Adjusting and Replacing Parking Brakes

Regular wheel brake service should be completed before adjusting the parking brake. Then check the parking brake for free movement of the parking brake cables in the conduits. If the cables drag, replace them. Check for worn equalizer and linkage parts. Replace any defective parts. Finally, check for broken strands in the cables. Replace any cable that has broken strands or shows signs of wear.

Testing Parking brake testing and adjustment procedures vary with the vehicle manufacturer. A common test is to raise the vehicle off the ground and apply the brake a specific number of "clicks." Once the brake is set, attempt to spin the rear wheels. If the wheels spin, release the parking brake and check the rear shoe-to-drum clearance and adjust if necessary. Recheck the parking brake. If the wheels still spin, adjust the parking brake until the brake holds. Release the brake and make sure the wheels spin and the brakes are not dragging.

Some technicians test the parking brake by parking the vehicle facing up on an incline of 30 degrees or less. Set the parking brake fully and place the transmission in neutral. The vehicle should hold steady. Reverse the vehicle position so it is facing down the incline and repeat the test. If the vehicle creeps or rolls in either case, the parking brake requires adjustment.

SUMMARY

- Drum brakes are still used on the rear wheels of many cars and light trucks.
- The drum is mounted to the wheel hub. When the brakes are applied, a wheel cylinder uses hydraulic power to press two brake shoes against the inside surface of the drum. The resulting friction between the shoe's lining and drum slows the drum and wheel.
- The brake's anchor pin acts as a brake shoe stop, keeping the shoes from following the rotating drum. This creates a wedging action that multiplies braking force.
- The shoes and wheel cylinder are mounted on a backing plate. Hardware, such as shoe return springs, holddown parts, and linkages are also mounted on the backing plate.
- The primary or leading shoe is toward the front of the vehicle while the secondary or trailing shoe is toward the rear of the vehicle.
- Brake lining can be attached to the shoes by riveting or a special adhesive bonding process.
- Brake drums act as a heat sink to dissipate the heat of braking friction. Drums can be refinished on a brake lathe provided the inside diameter is not increased above a safe limit (discard dimension).
- Servicing brakes requires performing a complete system inspection. Partial replacement of worn or damaged parts does not solve the braking problems and may ruin the new parts installed.
- When servicing brakes, extreme care must be taken to avoid generating asbestos dust.
- Wheel cylinders should be replaced if they show any signs of hydraulic fluid leakage or component wear.
- Drum brakes allow for the use of a simple parking brake mechanism that can be activated with a hand lever or foot pedal. This is a mechanical system, completely separate from the service brake hydraulic system.

Disc brakes resemble the brakes on a bicycle. The friction elements are in the form of pads, which are squeezed or clamped about the edge of a rotating wheel. With automotive disc brakes, this wheel is a separate unit mounted inboard of the wheel and tire, called the rotor **(Figure 52–1)**. The rotor is typically made of cast iron. Because the pads clamp against both sides of a rotor, both sides are machined smooth. The pads are attached to metal backings, which are actuated by pistons. The pistons are contained within a caliper assembly, which is a housing that wraps around the edge of the rotor. The caliper is mounted to the steering knuckle to stop it from rotating. The caliper contains the pistons and related seals, springs, bleeder screws, and boots as well as the cylinder(s) and fluid passages necessary to force the pads against the rotor.

Disc brakes offer four major advantages over drum brakes. Disc brakes are more resistant to

heat fade during high-speed brake stops or repeated stops. The design of the disc brake rotor exposes more surface to the air and thus dissipates heat more efficiently. They are also resistant to water fade because the rotation of the rotor tends to throw off moisture. The squeeze of the sharp edges of the pads clears the surface of water. Disc brakes perform more straight-line stops. Due to their clamping action, disc brakes are less apt to pull. Finally, disc brakes automatically adjust as pads wear.

Disc Brake Components and their Functions

The disc brakes used today are typically of two basic designs: fixed caliper **(Figure 52–2)** or floating caliper. There is also a sliding caliper, but its design is very similar to the floating caliper **(Figure 52–3)**. The only difference is that sliding calipers slide on surfaces that have been machined smooth for this purpose, and floating calipers slide on special pins or bolts. The disc brake, regardless of its design,

consists of a hub and rotor assembly, a caliper assembly, and the brake pads.

Rotors

The disc brake rotor has two main parts: the hub and the braking surface. The hub is where the wheel is mounted and may contain the wheel bearings. The braking surface is the machined surface on both sides of the rotor. It is carefully machined to provide a friction surface for the brake pads. The entire rotor is usually made of cast iron, which provides an excellent friction surface.

The size of the rotor braking surface is determined by the diameter of the rotor. Large and high performance cars, which require more braking energy, have large rotors. Smaller, lighter cars can use smaller rotors. Generally, manufacturers want to keep parts as small and light as possible while maintaining efficient braking ability.

The rotor is protected from water and dirt due to road splash by a splash shield bolted to the steering knuckle **(Figure 52–4)**. The outboard side is shielded by the vehicle's wheel. The splash shield and wheel also are important in directing air over the rotor to aid cooling.

Fixed and Floating Rotors Rotors are classified by their hub design. A **fixed rotor** may have the hub and the rotor cast as a single unit. The rotor illustrated in Figure 52–4 is an example of a fixed rotor. Another fixed design has the rotor bolted to the hub assembly. Removal requires taking off the hub, bearing, and rotor as a unit. The rotor is then unbolted from the hub and bearing. **Floating rotors** and hubs are made as two separate parts. The hub is a conventional casting and is mounted on wheel bearings or on the axle. The wheel studs are mounted in the hub and pass through the rotor center section **(Figure 52–5)**. One advantage of this design is that the rotor is less expensive and can be replaced easily and economically.

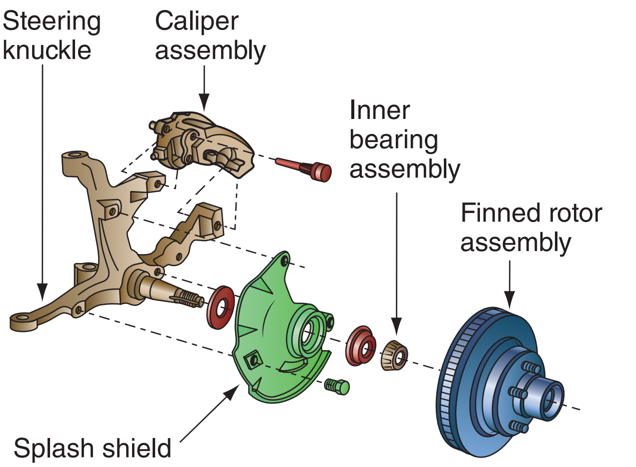

FIGURE 52–4 A splash shield protects the inboard side of the rotor.

Composite Rotors The need to reduce vehicle weight led to the development of composite rotors. Composite rotors are made of different materials,

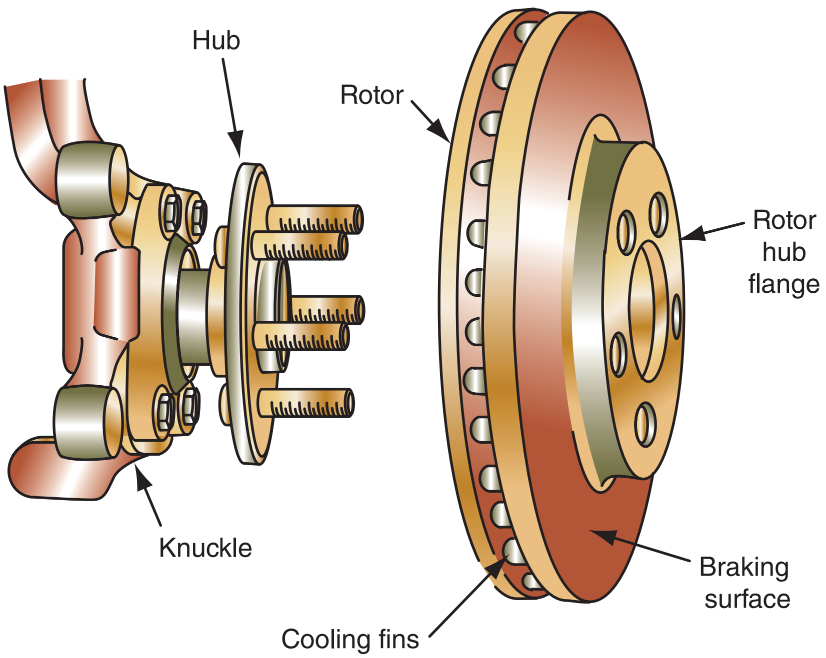

FIGURE 52–5 A rotor that is cast as a separate part and fastened to the hub is called a floating rotor.

usually cast iron and steel, to reduce weight. The friction surfaces and the hubs are cast iron, but the supporting parts of the rotor are made of lighter steel stampings **(Figure 52–6)**. The steel and iron sections are bonded to each other under heat and high pressure to form a one-piece finished assembly. Composite rotors may be fixed or floating rotors. Because the friction surfaces of composite rotors are cast iron, the wear standards are generally the same as they are for other rotors.

Ceramic Rotors In the late 1990s, Porsche first offered a carbon-ceramic brake option on the 911 GT2 and then on its 911 Turbo in 2000. Today, ceramic brakes are standard on many Ferraris and Lamborghinis and are available on Porsches, Bentleys, and some Corvettes **(Figure 52–7)**.

Ceramic brakes are costly, costing up to $15,000 on some vehicles, but weigh about one-half of a conventional rotor. This means they allow for lower unsprung weight that helps ride quality and handling and improves fuel economy. They also last four times longer than steel discs. Brake pads also last about three times longer. The brake pads designed to be used with ceramic discs contain a ceramic powder mixed with metal wires or particles. The pads have heat shields to prevent the heat from traveling through the system.

Ceramic brakes have excellent fade resistance and stopping power. Also, the vehicle's wheels stay cleaner because no black brake dust is released.

The disc assembly is a two-piece unit: a ceramic ring and a steel center piece or hub. The ring is bolted to the hub. The ring of the rotor is made of

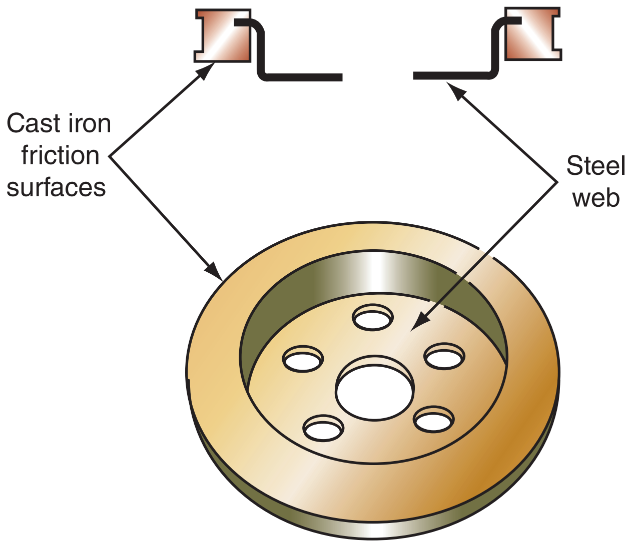

FIGURE 52–6 Composite rotors are made of different materials, usually cast iron and steel.

FIGURE 52–7 A carbon-ceramic brake assembly.

ceramic with carbon fibers arranged to strengthen the disc and conduct heat away from the surface. The ceramic material is based on silicon carbide, which is an extremely hard material with a crystal structure similar to that of diamond. The finished surface of the rotor looks like stone.

Solid and Ventilated Rotors A rotor may be solid or it may be ventilated. A solid rotor is simply a solid piece of metal with a friction surface on each side. A solid rotor is light, simple, cheap, and easy to manufacture. Because they do not have the cooling

capacity of a ventilated rotor, solid rotors usually are used on the rear of small to medium size cars of moderate performance. The rear brakes of performance-oriented vehicles—larger cars, trucks, and many SUVs-use vented rear rotors.

A ventilated rotor has cooling fins cast between the braking surfaces to increase the cooling area of the rotor. When the wheel is in motion, the rotation of these fins in the rotor also increases air circulation and brake cooling **(Figure 52–8)**. Although ventilated rotors are larger and heavier than solid rotors, these disadvantages are more than offset by their better cooling ability and heat dissipation.

Some ventilated rotors have cooling fins that are curved or formed at an angle to the hub center **(Figure 52–9)**. These fins increase the centrifugal force on the rotor airflow and increase the air volume that removes heat. Such rotors are called unidirectional rotors because the fins only work properly when the rotor rotates in one direction. Therefore, unidirectional rotors cannot be interchanged from the right side to the left side on the car.

Drilled vs. Slotted Rotors Many high-performance vehicles are fitted with cross-drilled rotors **(Figure 52–10)**. The idea behind having holes through the rotor is simply to allow heat, gases, and dirt to escape. In addition, the edges of the holes give a place for the pads to grab. They, however, also decrease the overall surface area of the rotor, which reduces the thermal capacity of the discs and the discs have a poor service life. The latest trend is to cut a series of tangential slots or channels into the surface. These slots do the same thing as the holes without the disadvantages.

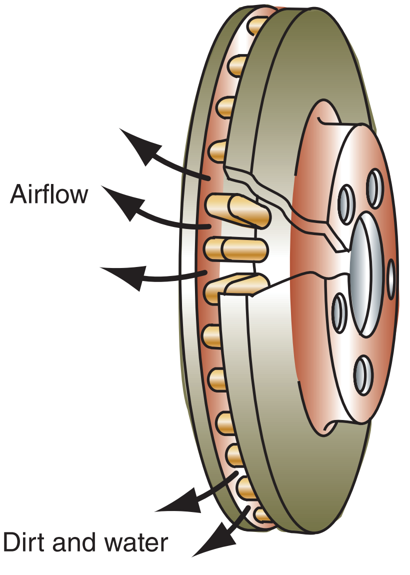

FIGURE 52–8 A ventilated rotor has cooling fins cast between the braking surfaces to increase the cooling area of the rotor.

Rotor Hubs and Wheel Bearings

Tapered roller bearings, which are installed in the wheel hubs, were common on the front wheels of RWD and the rear wheels of FWD vehicles. Normally late-model vehicles do not use tapered roller bearings, however, there are many vehicles still on the

road that have them. The tapered roller bearing has two main parts: the inner bearing cone and the outer bearing cup. The bearing cone is an assembly that contains steel tapered rollers. The rollers ride on an inner cone-shaped race and are held together by a bearing cage. The bearing fits into the outer cup, or race, which is pressed into the hub. This provides two surfaces, an inner cone and outer cup, for the rollers to ride on. The bearings are held in place with a thrust washer, nut, locknut, and cotter pin. A dust cap fits over the assembly to keep dirt out and lubricant in. A seal on the inboard side prevents lubricant from escaping at this end.

Caliper Assembly

A brake caliper converts hydraulic pressure into mechanical force. The caliper housing is usually a one-piece construction of cast iron or aluminum and has an inspection hole in the top to allow for lining wear inspection. The housing contains the cylinder bore(s). In the cylinder bore is a groove that seats a square-cut seal. This groove is tapered toward the bottom of the bore to increase the compression on the edge of the seal that is nearest hydraulic pressure. The top of the cylinder bore is also grooved as a seat for the dust boot. A fluid inlet hole is machined into the cylinder bore and a bleeder valve is located near the top of the casting **(Figure 52–11)**.

A caliper can contain one, two, four, or six cylinder bores and pistons that provide uniform pressure distribution against the brake's friction pads. The pistons are relatively large in diameter and short in stroke to provide high pressure on the friction pad assemblies with a minimum of fluid displacement.

Basically, the hydraulics of disc brakes are the same as for drum brakes, in that the master cylinder piston forces the brake fluid into the wheel cylinders and against the wheel pistons.

The disc brake piston is made of steel, aluminum, or fiberglass-reinforced phenolic resin (a polymer plastic). Steel pistons are usually nickel-chrome plated for improved durability and smoothness. The top of the pistons is grooved to accept the dust boot that seats in a groove at the top of the cylinder bore and also in a groove in the piston. The dust boot prevents moisture and road contamination from entering the bore.

A piston hydraulic (square-cut) seal prevents fluid leakage between the cylinder bore wall and the piston. This rubber sealing ring also acts as a retracting mechanism for the piston when hydraulic pressure is released, causing the piston to return in its bore **(Figure 52–12)**. When hydraulic pressure is diminished, the seal functions as a return spring to retract the piston.

In addition, as the disc brake pads wear, the seal allows the piston to move farther out to adjust automatically for the wear without allowing fluid to leak. Since the brake pads need to retract only slightly after they have been applied, the piston moves back only slightly into its bore. The additional brake fluid

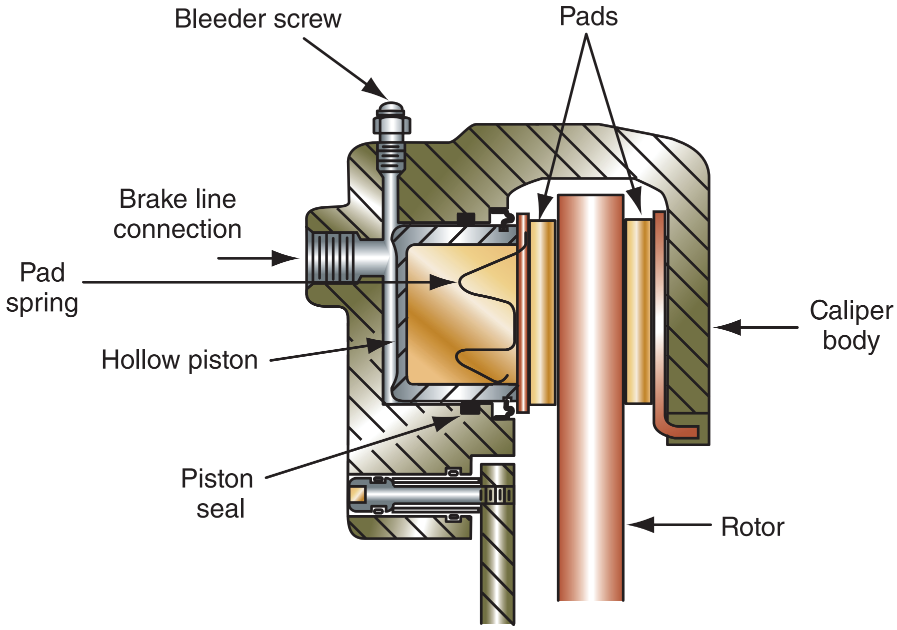

FIGURE 52–11 Cross section of a typical caliper.

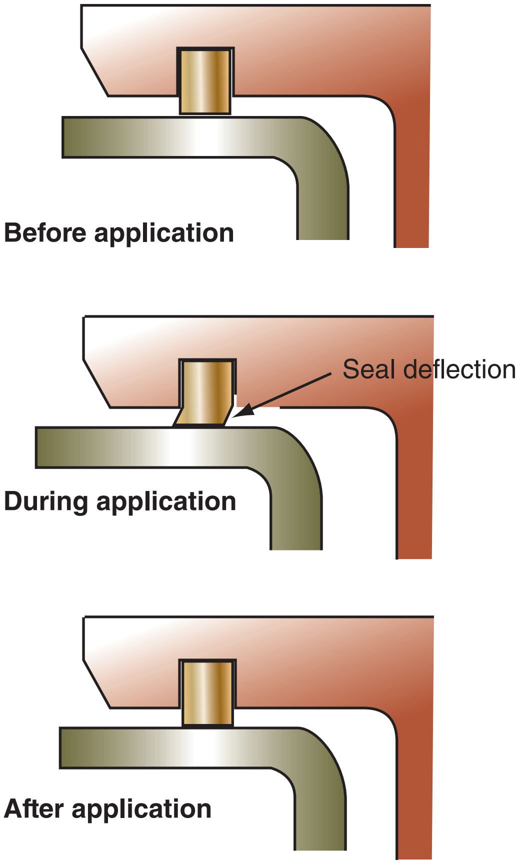

FIGURE 52–12 The deflection of a square-cut seal during brake application and brake release.

in the caliper bore keeps the piston out and ready to clamp the surface of the rotor.

Fixed Caliper Disc Brakes **Fixed caliper** disc brakes have a caliper assembly that is bolted in a fixed position and does not move when the brakes are applied. The pistons in both sides of the caliper come inward to force the pads against the rotor **(Figure 52–13)**. Fixed calipers typically have two to six pistons based on the size of the brake and the performance of the vehicle.

Fixed calipers may be one or a two-piece design. Also called a monobloc caliper, one-piece designs are made from a single piece of aluminum to reduce weight. Two-piece calipers are bolted together and are less expensive than one-piece calipers. Fluid passages may be machined into the caliper body or external transfer tubes (steel brake lines) route fluid to both sets of pistons.

Floating Caliper Disc Brakes A typical **floating caliper** disc brake is a one-piece casting that has one hydraulic cylinder and a single piston. The caliper is attached to the spindle anchor plate with two threaded locating pins **(Figure 52–14)**. A Teflon sleeve separates the caliper housing from each pin and the caliper slides back and forth on the pins as

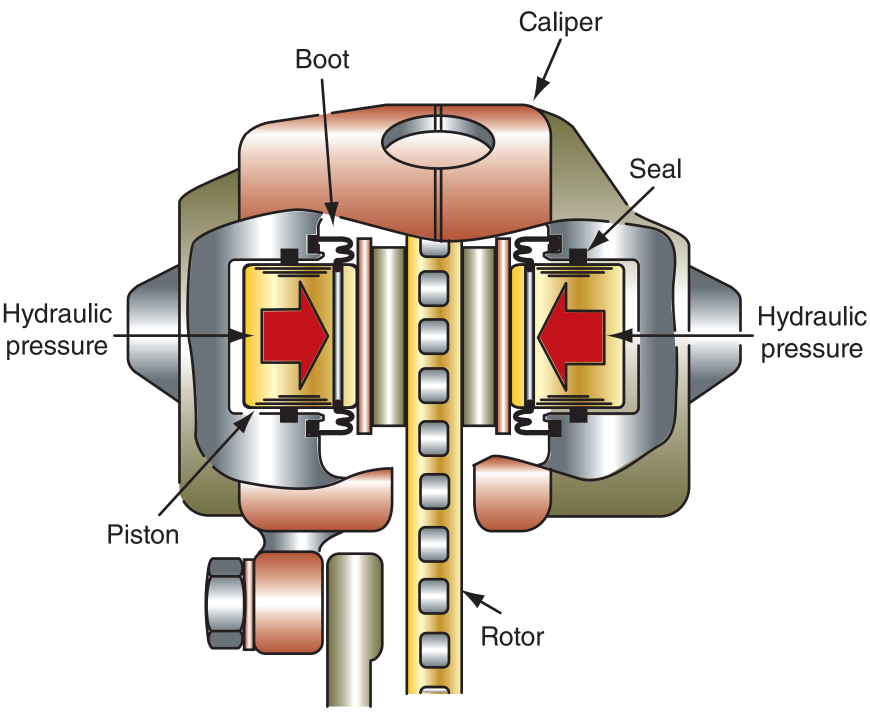

FIGURE 52–13 The caliper of a fixed caliper assembly is bolted in a fixed position and does not move when the brakes are applied.

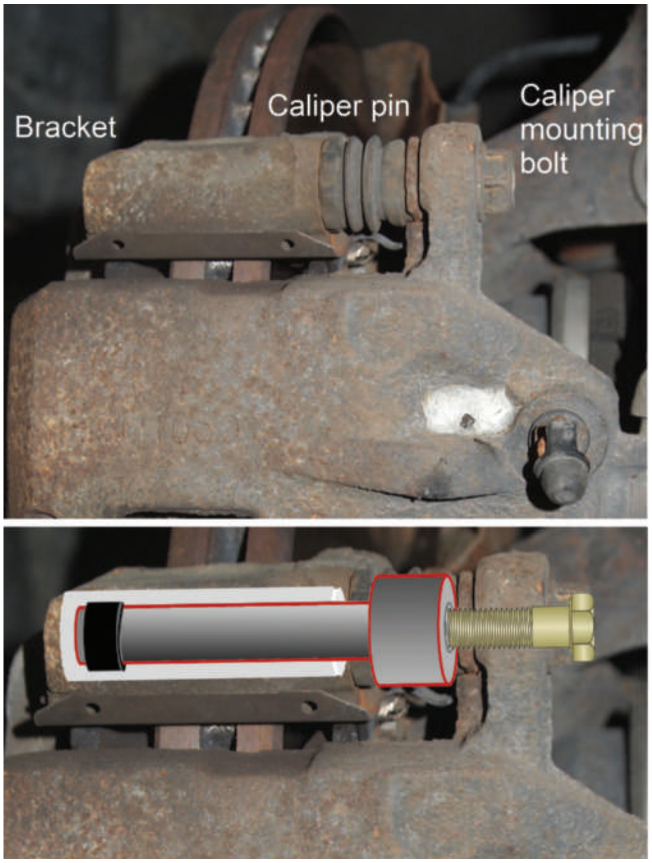

FIGURE 52–14 The caliper bolt attaches the caliper to the pin inside the bracket.

the brakes are actuated. When the brakes are applied, hydraulic pressure builds in the cylinder behind the piston and seal. Because hydraulic pressure exerts equal force in all directions, the piston moves evenly out of its bore.

The piston presses the inboard pad against the rotor. As the pad contacts the revolving rotor, greater resistance to outward movement is increased, forcing pressure to push the caliper away from the piston. This action forces the outboard pad against the rotor **(Figure 52–15)**. However, both pads are applied with equal pressure.

Sliding Caliper Disc Brakes With a **sliding caliper** assembly, the caliper slides or moves sideways when the brakes are applied. As mentioned previously, in operation, these brakes are almost identical to the floating type. But unlike the floating caliper, the sliding caliper does not float on pins or bolts attached to the anchor plate. It has angular machined surfaces at each end that slide in mating machined surfaces on the anchor plate. This is where the caliper slides back and forth.

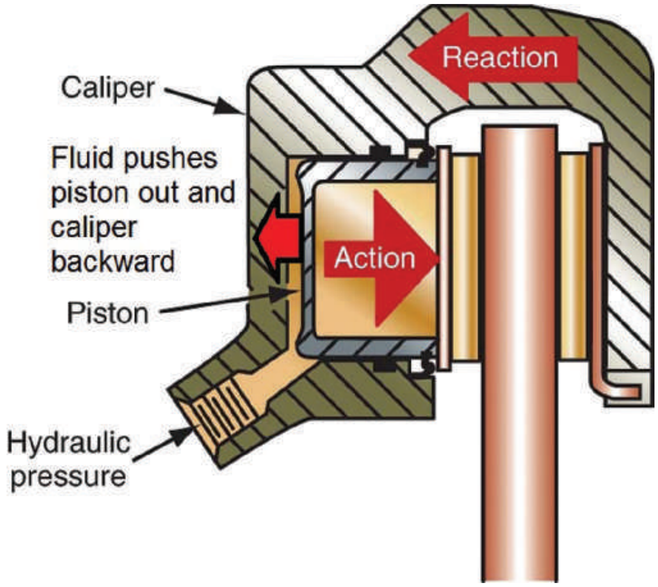

FIGURE 52–15 Operation of a floating caliper.

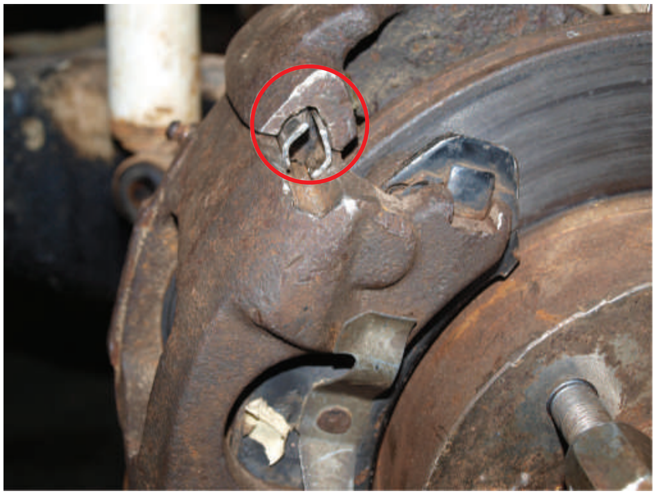

FIGURE 52–16 Some sliding calipers use a support key to locate and support the caliper in the anchor plate.

Some sliding calipers use a support key to locate and support the caliper in the anchor plate **(Figure 52–16)**. The caliper support key is inserted between the caliper and the anchor plate. A worn support key may cause tapered brake pad wear. Always inspect the support keys when replacing brake pads. Also make sure they are lubricated when reassembling the unit.

Brake Pad Assembly

Brake pads are metal plates with the linings either riveted or bonded to them. Pads are placed at each side of the caliper and straddle the rotor. The

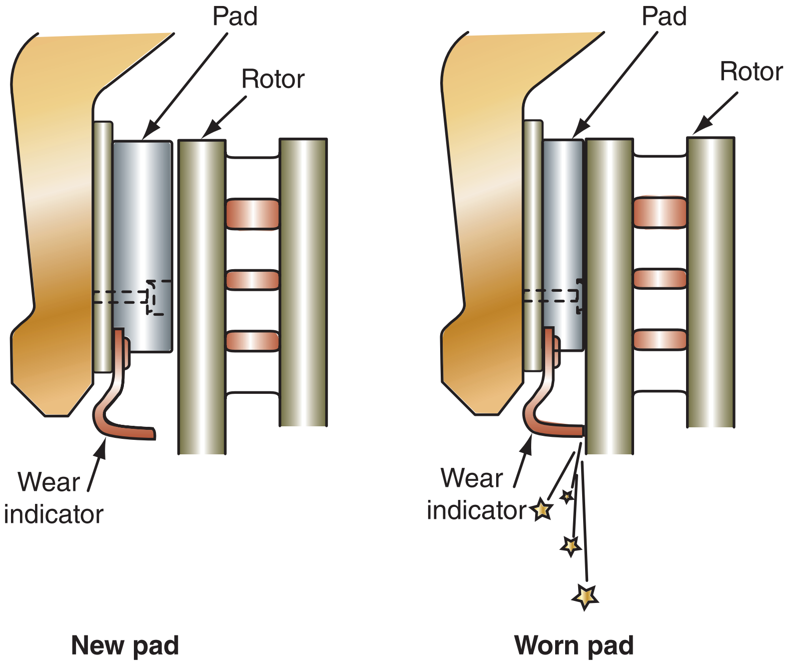

FIGURE 52–17 Operation of the wear indicator.

linings are made of semimetallic or other non-asbestos material.

Disc Pad Wear Sensors Some brake pads have wear indicators. The three most common design wear sensors are audible, visual, and tactile.

Audible sensors are thin, spring steel tabs that are riveted to or installed onto the edge of the pad's backing plate and are bent to contact the rotor when the lining wears down to a point that replacement is necessary. At that point, the sensor causes a high-pitched squeal whenever the wheel is rotating, except when the brakes are applied. Then the noise goes away. The noise gives a warning to the driver that brake service is needed and perhaps saves the rotor from destruction **(Figure 52–17)**.

Pads often have grooves cut into the lining **(Figure 52–18)**. These not only help with venting dust and pad cooling but also can be used to indicate when the pads need to be replaced. The grooves typically do not completely bisect the pad, instead, they leave 1 to 2 millimeters of the lining uncut. Once the pad wears to the bottom of the groove, the pad is due for replacement.

Some vehicles have systems with an electronic wear indicator in the disc brake pads. As the pad wears to a predetermined point, a warning light in the instrument panel is illuminated by the wear sensors. In some systems, a small pellet is contained in the brake pad's friction material. The pellets are wired in series or in parallel to the red brake warning lamp circuit **(Figure 52–19)** and complete the lamp circuit when the pellets contact the rotor.

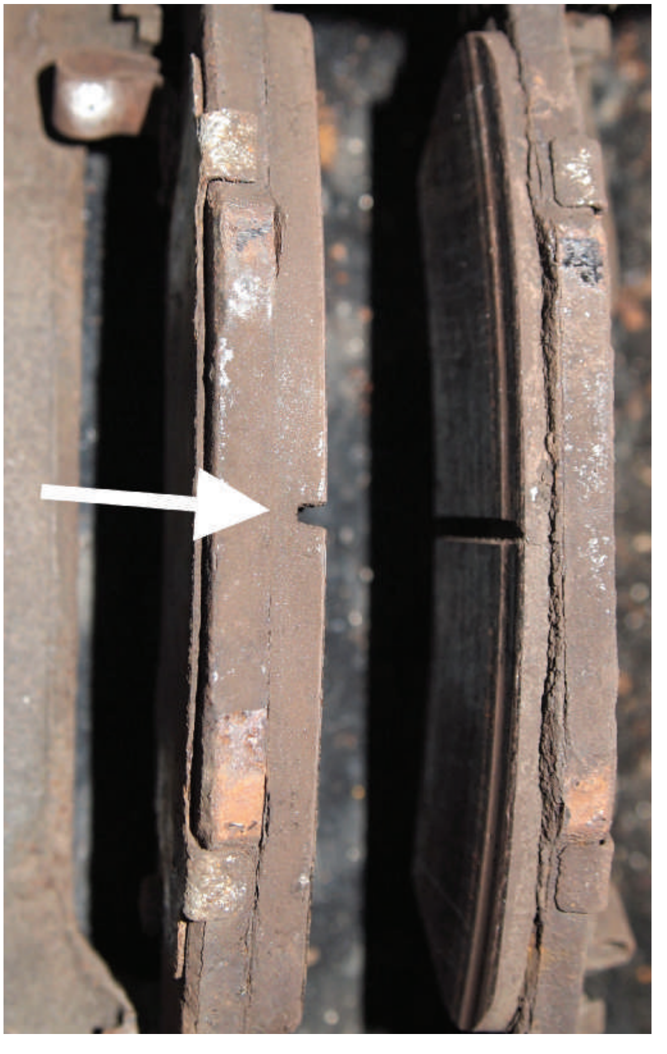

FIGURE 52–18 The groove cut into the lining serves several purposes.

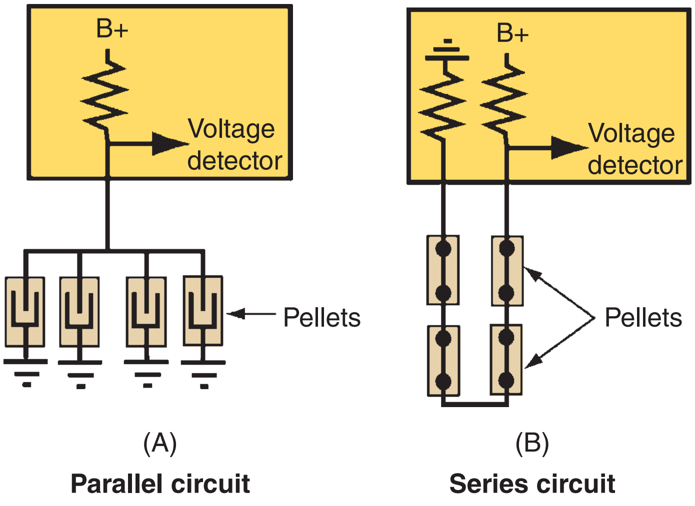

FIGURE 52–19 Electronic pad wear sensors can be wired in parallel or in series with the warning lamp. The pellets are embedded in the brake pads.

Rear-Wheel Disc Brakes

Rear-wheel disc brake calipers may be fixed, floating, or sliding, and all of these designs work in the same way as when they are used at the front wheels. The only difference between a front and rear disc brake caliper is that the rear disc brake caliper needs a parking brake. Four-wheel disc brake installations must have some way to apply the rear brakes when the parking brake is set.

Rear Disc/Drum (Auxiliary Drum) Parking Brake

The rear disc/drum or auxiliary drum parking brake arrangement is found on many cars, light-duty trucks, and SUVs. On these brakes, the inside of each rear wheel hub and rotor assembly is used as the parking brake drum **(Figure 52–20)**. A pair of small brake shoes is mounted on a backing plate that is bolted to the axle housing or the hub carrier. These parking brake shoes operate independently of the service brakes. They are applied by linkage and cables from the control pedal or lever. The cable at each wheel operates a lever and strut that apply the shoes in the same way that rear drum parking brakes work.

The assembly (often called the drum-in-hat system) is a smaller version of a drum brake and is serviced much like any other drum brake. However, they do not have self-adjusters. The parking brakes must be adjusted manually with star wheels that are accessible through the backing plate or through the outboard surface of the drum **(Figure 52–21)**.

CUSTOMER CARE

Excessive heat liquefies the resin binder that holds the brake pad material together. Once liquefied, the binder rises to the surface of the pad to form a glaze. A glazed pad may cause squealing because more heat is needed to achieve an amount of friction equal to a pad in good condition. One common cause of pad glazing is the improper break-in of the pads. Remember to inform customers that unnecessary hard braking during the first 200 miles (320 km) of a pad's life can generate enough heat to glaze the pads and ruin the quality of the work just performed. There are pads now available that require no break-in time.

FIGURE 52–20 On some rear disc brakes, the inside of the rear wheel hub and rotor assembly is used as the parking brake drum.

Late-model GM trucks use an expandable, single metal band covered with friction material inside the parking brake drum that is machined on the inside of the rear brake disc.

Caliper-Actuated Parking Brakes

Some floating or sliding caliper rear disc brakes mechanically apply the calipers' pistons to lock the pads against the rotors for parking. All caliper-actuated

FIGURE 52–21 The auxiliary drum parking brakes are adjusted through a window in the backing plate.

parking brakes have a lever that protrudes from the inboard side of the caliper. These levers are operated by linkage and cables from the parking brake control pedal or lever.

The two most common types of caliper-actuated parking brakes are the screw-and-nut type and the ball-and-ramp type. A few imported cars have a third type that uses an eccentric shaft and a rod to apply the caliper piston. An eccentric acts like a cam. One portion of the shaft is oval-shaped. As the shaft rotates, the high part of the oval pushes the operating rod out to apply the brakes.

General Motors' floating caliper rear disc brakes are the most common example of the screw-and-nut parking brake mechanism **(Figure 52–22)**. The caliper lever is attached to an actuator screw inside the caliper that is threaded into a large nut. The nut, in turn, is splined to the inside of a large cone that fits inside the caliper piston. When the parking brake is applied, the caliper lever rotates the actuator screw. Because the nut is splined to the inside of the cone, it cannot rotate, so it forces the cone outward against the inside of the piston, forcing it outward. Similarly, the piston cannot rotate because it is keyed to the brake pad, which is fixed in the caliper. The piston then applies the inboard brake pad, and the caliper slides as it does for service brake operation and forces the outboard pad against the rotor. An adjuster spring inside the nut and cone rotates the nut outward when the parking brakes are released to provide self-adjustment. Rotation of the nut takes up clearance as the brake pads wear.

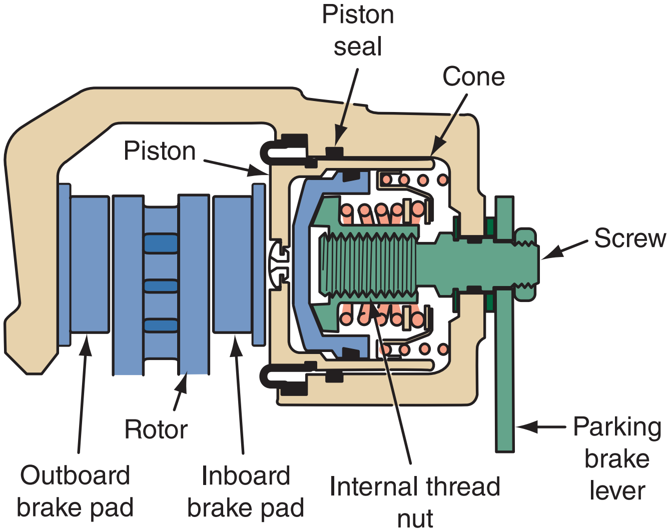

FIGURE 52–22 A GM screw-and-nut parking brake mechanism for a disc brake.

Ford's floating caliper rear disc brakes are the most common example of the ball-and-ramp parking brake mechanism **(Figure 52–23)**. The caliper lever is attached to a shaft inside the caliper that has a small plate on the other end. Another plate is attached to a thrust screw inside the caliper piston. The two plates face each other, and three steel balls separate them. When the parking brake is applied, the caliper lever rotates the shaft and plate. Ramps in the surface of the plate force the balls outward against similar ramps in the other plate. As the plates move farther apart, the thrust screw forces the piston outward. The thrust screw cannot rotate because

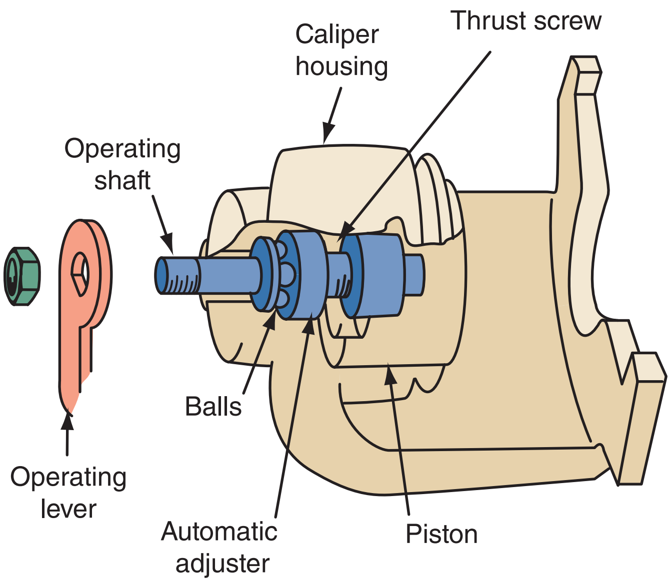

FIGURE 52–23 A Ford ball-and-ramp parking mechanism for a disc brake.

it is keyed to the caliper. The piston then applies the inboard brake pad, and the caliper slides as it does for service brake operation and forces the outboard pad against the rotor. When the piston moves away from the thrust screw, an adjuster nut inside the piston rotates on the screw to take up clearance and provide self-adjustment. A drive ring on the nut keeps it from rotating backward.

Another way to tighten the pads against the rotor when the parking brake is applied is to use a threaded, spring-loaded pushrod. As the parking brakes are applied, a mechanism rotates or unscrews the pushrod, which in turn pushes the piston out.

Electrically Operated Parking Brake

Many new vehicles use electronic parking brakes. To set or release the brake, the driver holds the brake pedal down and presses or pulls the Parking Brake button **(Figure 52–24)**. The brake control module commands the electric motor(s) to apply the parking brake. Application can be direct, meaning the motor is attached to the back of the rear caliper **(Figure 52–25)** or the motor may pull a parking brake cable attached to a traditional parking brake caliper. To release, press and hold the brake pedal and then the Parking Brake button.

These systems also have an automatic release function. If the driver puts the vehicle into gear and starts to drive off without pressing the button, the computer will automatically release the brake to prevent damage. In both designs, the motors are not designed to be used to stop the vehicle in the event the service brakes fail; instead, the system is used only for holding the vehicle in place when it is parked.

Servicing these systems, even installing rear brake pads often requires the use of a scan tool.

Disc Brake Diagnosis

Many problems experienced on vehicles with disc brakes are the same as those evident with drum brake systems. Some problems occur only with disc brakes. Before covering the typical complaints, it is important to remind you to get as much information as possible about the complaint from the customer. Then road test the vehicle to verify the complaint. A complete inspection of the rotor, caliper, and pads should be done any time you are working on the brakes.

What follows is a brief discussion of common complaints and their typical causes.

Warning Lights

Today's vehicles are normally equipped with more than one brake warning light on the instrument panel. Regardless of what warning light is lit, it is an indication of warning to the driver. You need to understand what would cause the different lights to illuminate in order to take care of the problem. Keep in mind, a vehicle may have one, two, or all of these lights **(Figure 52–26)**.

FIGURE 52–26 Typical brake warning lamps.

The red warning light indicates there is a problem in the regular brake system, such as low brake fluid levels or that the parking brake is on. A low fluid light may be present in addition to the red brake warning light. Whenever the fluid is low, you should suspect a leak or very worn brake pads.

The yellow or amber brake warning light is tied into the antilock brake system (ABS). This light turns on for two reasons: the ABS is performing a self-test or there is a fault in the ABS.

A blue or yellow warning light lets the driver know the wheels are slipping because of poor road conditions.

Pulsating Pedal

Customers will feel a vibration or pulsation in the brake pedal when the brakes are applied if a brake rotor is warped. A warped brake rotor is one that no longer has parallel friction surfaces or has side-to-side movement, called lateral runout. If this symptom exists, check the rotors for runout and parallelism, described later in this chapter. A warped rotor may need to be replaced and can be caused by improper tightening of the wheel lug nuts. In fact, uneven lug nut torque can cause a pulsating brake pedal. You should be aware that pedal pulsation is normal on vehicles with ABS when the ABS is working.

Spongy Pedal

With a spongy pedal, the customer will probably feel the need to pump the brake pedal to get good stopping ability. The complaint may also be described as a soft pedal. This problem is typically caused by air in the hydraulic system. Although bleeding the system may remove the air, you should always question how the air got in there. Check for leaks and for proper master cylinder operation.

A spongy brake pedal can be caused by excessive flexing in the pads or caliper and bracket. If the caliper is able to flex or move too much during braking, the pedal will travel further and be less firm.

Hard Pedal

The driver's complaint of a hard pedal normally indicates a problem with the power brake booster. However, it can also be caused by a restricted brake line or hose. Carefully check the lines and hoses for damage. Feel the brake hoses. If they seem to have lost their rigidity, the hose may have collapsed on the inside, and this is causing the restriction. Make sure the brake hoses have not been twisted. Incorrect caliper installation can twist and restrict the hose. A hard pedal can also be caused by frozen caliper or wheel cylinder pistons.

Dragging Brakes

Dragging brakes make the vehicle feel as if it has lost or is losing power as it drives down the road. The problem also wastes a lot of fuel and generates destructive amounts of heat that can cause serious brake damage and brake failure. While trying to find the cause of this problem, check the parking brake first. Make sure it is off. Check the rear wheels to make sure the parking brakes are released when they should be. If the problem is not in the parking brakes, check for restricted brake hoses keeping pressure applied to the calipers. Inspect the calipers and wheel cylinders for sticky or seized pistons.

Seized caliper pistons can be freed by using a pry bar or C-clamp to push the pistons back into the calipers, as shown in **Figure 52–27**. Position the pry bar to pull the caliper outward, forcing the piston backward into its bore. If the piston does not retract, loosen the bleeder valve and retry. If the caliper still does not move, the piston is likely seized. If the piston retracts, the brake hose is likely the cause of the problem.

Grabbing Brakes

When the brakes seem to be overly sensitive to pedal pressure, they are grabbing. Normally this problem is caused by contaminated brake linings. If the linings are covered or saturated with oil, find the source of the oil and repair it. Then replace the pads and refinish or replace the rotor.

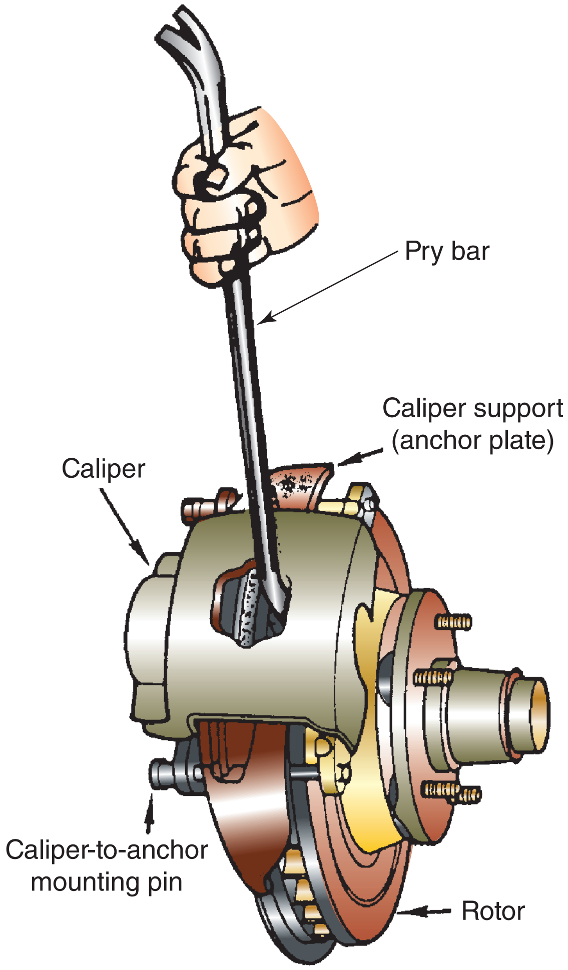

FIGURE 52–27 A large screwdriver or pry bar can be used to move a piston back into its bore in the caliper.

Noise

If the customer's complaint is noisy brakes, verify during the road test that the problem is in the brakes. If the noise is caused by the brakes, pay attention to the type of noise and let that lead you to the source of the problem. Remember, some brake pads have wear sensors that are designed to make a high-pitched squeal when the pads are worn. Other causes could be the rotor rubbing against the splash shield or that something has become wedged between the rotor and another part of the vehicle. Noise may also be caused by failure to install all of the hardware when replacing a caliper or brake pads.

Other sources of noise include the pads themselves. Depending on the lining materials, some pads are more prone to make noise. These noises can be like a light wire brush against metal sound, grinding, or high-pitched squeal depending on the pad.

Pulling

When a vehicle drifts or pulls to one side while cruising or when braking, the cause could be in the brake system or in the steering and suspension system. Check the inflation of the tires, the tires' tread condition, and verify that the tires on each axle are the same size. Check the operation of the brakes. If only one front wheel is actually doing the braking, the vehicle will seem to stumble or pivot on that one wheel. If no problems are found in the brake system, suspect an alignment or suspension problem such as worn control arm bushings.

Service Guidelines

The following general service guidelines apply to all disc brake systems and should always be followed:

- Be sure the vehicle is properly centered and secured on stands or a hoist.
- If the vehicle has antilock brakes, depressurize the system according to the procedures given in the service information.
- Before any service is performed, check the following:
  - Tires for excessive wear or improper inflation
  - Wheels for bent or warped rims
  - Wheel bearings for looseness or wear
  - Suspension components to see if they are worn or broken
  - Brake fluid level and condition
  - Master cylinder, brake lines or hoses, and each wheel for leaks
  - Parking brake operation
- Before you remove a brake hydraulic part, use a pedal depressor to slightly depress the brake pedal. This closes the master cylinder's ports and prevents fluid from draining. It also makes the bleeding process easier after the system is reassembled.
- Before beginning brake work, remove about two-thirds of the brake fluid from the master cylinder's reservoir. If this is not done, the fluid could overflow and spill when the pistons are forced back into the caliper bore. Many technicians open the caliper bleeder screw and run a hose to a container to catch the fluid that is expelled **(Figure 52–28)**. This prevents dirty brake fluid from being forced back into the ABS control unit.

FIGURE 52–28 When you open the caliper bleeder screw, attach a hose inserted into a container to catch the fluid that is expelled.

- If the bleeder screws are frozen tight with corrosion, it is sometimes possible to free them by tapping on the caliper body at the bleeder with a hammer. If the bleeder screws cannot be loosened, the entire caliper is probably in bad shape so it is best to replace the entire unit.
- During servicing, grease, oil, brake fluid, or any other foreign material must be kept off the brake linings, caliper, surfaces of the disc, and external surfaces of the hub. Handle the brake disc and caliper in such a way to avoid damage to the disc.
- When a hydraulic hose is disconnected, plug it to prevent foreign material from entering.
- Never permit the caliper assembly to hang with its weight on the brake hose. Support it on the suspension or hang it by away from the assembly **(Figure 52–29)**.
- When using compressed air to remove the caliper pistons, avoid high pressures. A safe pressure to use is 30 psi (207 kPa).
- Clean the hydraulic brake components in either denatured alcohol or clean brake fluid. Do not use mineral-based cleaning solvent such as gasoline, kerosene, carbon tetrachloride, acetone, or paint thinner to clean the caliper. It causes rubber parts to become soft and swollen in an extremely short time.
- With the recommended lubricant, lubricate all moving parts, such as the caliper housing or mounting bracket to ensure a free-moving action.
- Obtain a firm brake pedal after servicing the brakes and before moving the vehicle. Be sure to road test the vehicle.

FIGURE 52–29 Never permit the caliper assembly to hang with its weight on the brake hose. Support it on the suspension or hang it away from the assembly.

- Before installing the lug nuts to fasten the wheels, check the studs for signs of damage or stretching. If any defects are found, replace the stud.

GO TO Chapter 40 for information on replacing the wheel studs.

- Always torque all brake fasteners to specifications. Torque the lug nuts when installing a wheel onto the vehicle. Never use an impact gun to tighten the lug nuts. Warpage of the rotor could result if an impact gun is used.

Warning! Do not use a torch to heat a frozen bleeder screw. This can damage the seals inside the caliper and possibly cause the brake hose to rupture.

General Caliper Inspection and Servicing

Frequently, caliper service involves only the removal and installation of the brake pads. However, since the new pads are thicker than the worn-out set they replace, they locate the piston farther back in the bore where dirt and corrosion might cause the seals to leak. For this reason, it is often good practice to carefully inspect the calipers whenever installing new pads. Of course, it is also good practice to true-up or replace the rotors when replacing brake pads.

When bench testing or servicing a caliper assembly, use a vise that is equipped with protector jaws. Excessive vise pressure causes bore and piston distortion.

Caliper Removal

To be able to replace brake pads, service the rotor, or to replace the caliper, the caliper must be removed. The procedure for doing this varies according to caliper design. Always follow the specific procedures given in the service information. Use the following as an example of these procedures:

Brake Pad Removal

Sliding or floating calipers typically must be lifted off the rotor for pad replacement. However, some designs allow the caliper to be tilted out of the way, allowing the pads to be removed and replaced without removing the caliper **(Figure 52–33)**. Even if caliper removal is not necessary, it is a good practice to remove it to allow for closer inspection and cleaning of the components.

Fixed calipers might have pads that can be replaced by removing the retaining pins or clips instead of having to lift the entire caliper off. Brake pads may be held in position by retaining pins, guide pins, or a support key. Note the position of the shims, antirattle clips, keys, bushings, or pins during disassembly. A typical procedure for replacing brake pads is outlined in Photo Sequence 49.

If you are only replacing the pads, lift the caliper off the rotor and hang it up by a wire. Remove the pads. Remove the old sleeves and bushings and install new ones. Replace the rusty pins to ensure free movement.

Brake Pad Inspection

Disc brake pads should be checked periodically. Some calipers have inspection holes in the caliper body. If they do not, the pads can be inspected from the outer ends of the caliper.

PROCEDURE

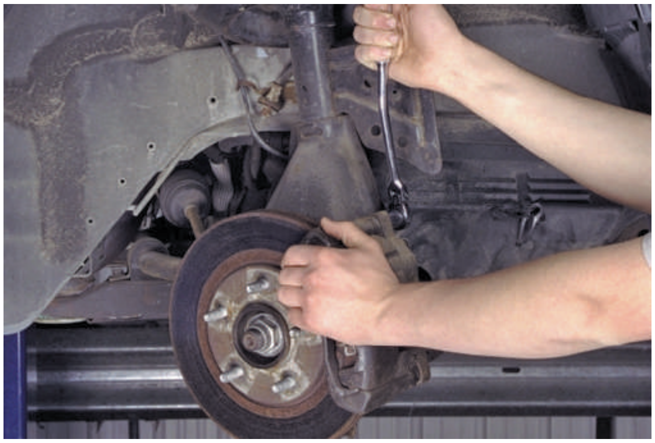
1. Remove about two-thirds of the brake fluid from the master cylinder.
2. Raise the vehicle and remove the wheel and tire assembly.
3. On a sliding or floating caliper, install a C-clamp with the solid end of the clamp on the caliper housing and the screw end on the metal portion of the outboard brake pad. Tighten the clamp until the piston bottoms in the caliper bore **(Figure 52–30)**, then remove the clamp. Bottoming the piston allows room for the brake pad to slide over the ridge of rust that accumulates on the edge of the rotor.
4. On threaded-type rear calipers, the piston must be rotated to depress it, which requires a special tool. This is discussed later in this chapter.
5. If only the brake pads are to be replaced, do not disconnect the brake hose. If rebuilding or replacing the caliper, disconnect the brake hose from the caliper and remove the copper gaskets or washer and cap the end of the brake hose. Remove the two mounting brackets to the steering knuckle bolts. Support the caliper when removing the second bolt to prevent the caliper from falling.
6. On a sliding caliper, remove the top bolts, retainer clip, and antirattle springs **(Figure 52–31)**. On a floating caliper, remove the two special pins that hold the caliper to the anchor plate **(Figure 52–32)**. On a fixed caliper, remove the bolts holding it to the steering knuckle. On all three types, get the caliper off by prying it straight up and lifting it clear of the rotor.

Removing and Replacing Brake Pads

P49-1 Front brake pad replacement begins with removing brake fluid from the master cylinder reservoir.

P49-2 Raise the car. Make sure it is safely positioned on the lift. Remove its wheel assemblies.

P49-3 Inspect the brake assembly. Look for signs of fluid leaks, broken or cracked lines, or a damaged brake rotor. If any problem is found, correct it before installing the new brake pads.



P49-4 Loosen the bolts and remove the pad locator pins.

P49-5 Lift and rotate the caliper assembly from the rotor.

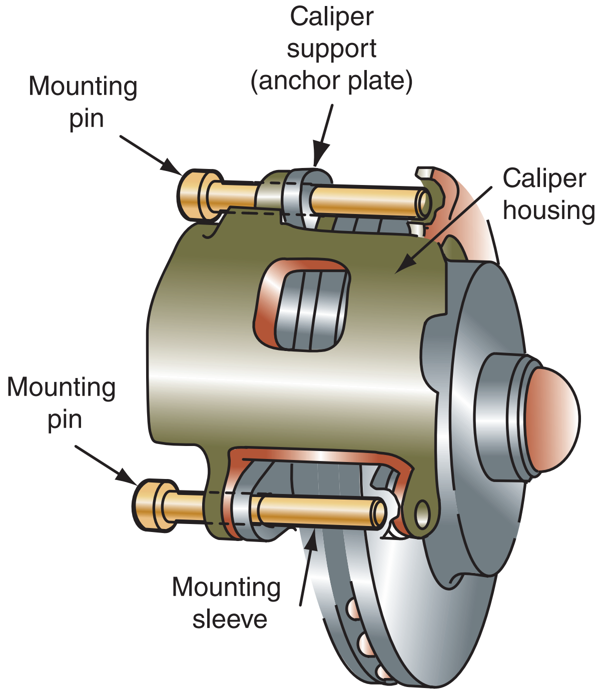

FIGURE 52–32 To remove a floating caliper, remove the pins holding it to the steering knuckle or bracket.

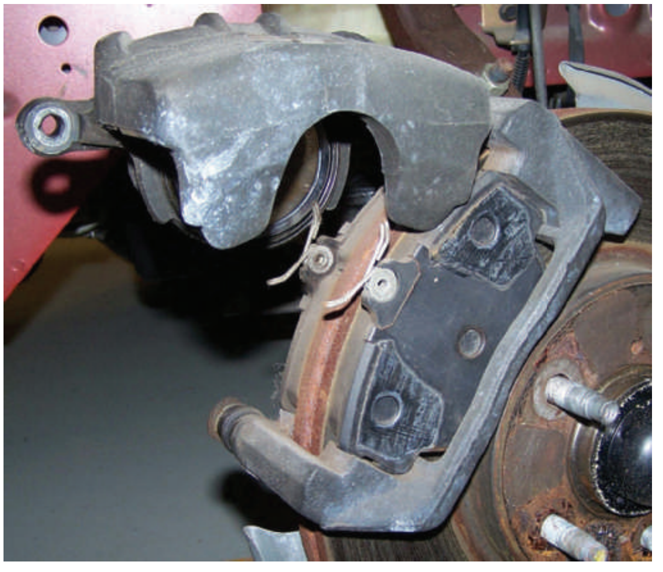

FIGURE 52–33 Some calipers can be rotated up on its upper mounting pin to replace the brake pads.

If you are not sure the pads are worn enough to warrant replacement, measure them at the thinnest part of the pad. Compare this measurement to the minimum brake pad lining thickness listed in the service information **(Figure 52–34)**, and replace the pads if needed. Typically, if the friction material remaining on the backing plate is less than ⅛-inch (3.175 mm), the pads should be replaced.

When a pad on one side of the rotor has worn more than the other side, there is uneven wear. Uneven pad wear often means the caliper is sticking and not giving equal pressure to both pads. On a sliding caliper, the problem could be caused by poor lubrication or deformation of the machined sliding areas on the caliper and/or anchor plate. Rust buildup on the pad guides is a common cause of the pads not sliding properly.

Caliper Disassembly

If the caliper must be rebuilt, it should be taken to the workbench for servicing. Drain any brake fluid

SHOP TALK

Most often, calipers are replaced rather than rebuilt. The old caliper is sent back to the manufacturer as a core. The following overview for rebuilding is intended only to give you an understanding of what may be done. Always refer to the appropriate service information when rebuilding a caliper.

from the caliper by way of bleeder screws. Remove the bleeder valve protector, if so equipped.

On a floating caliper, examine the mounting pins for rust that could limit travel. Most manufacturers recommend that these pins and their bushings be replaced each time the caliper is removed. This is a good idea because the pins are inexpensive and a good insurance against costly comebacks. On a fixed caliper, check the pistons for sticking and rebuild the caliper if this problem is found.

To disassemble the caliper, the piston and dust boot must first be removed. Place the caliper face down on a workbench **(Figure 52–35)**. Insert the used outer pad or a block of wood into the caliper. Place a folded shop towel on the face of the lining to cushion the piston. Apply low air pressure (NEVER MORE THAN 30 PSI) to the fluid inlet port of the caliper to force the piston from the caliper housing.

Caution! Wear safety glasses while disassembling the caliper to protect your eyes from spraying brake fluid.

Warning! Be careful to apply air pressure very gradually. Be sure there are enough shop rags to catch the piston when it comes out of the bore. Never place your fingers in front of the piston for any reason when applying compressed air. Personal injury could occur if the piston is popped out of the bore.

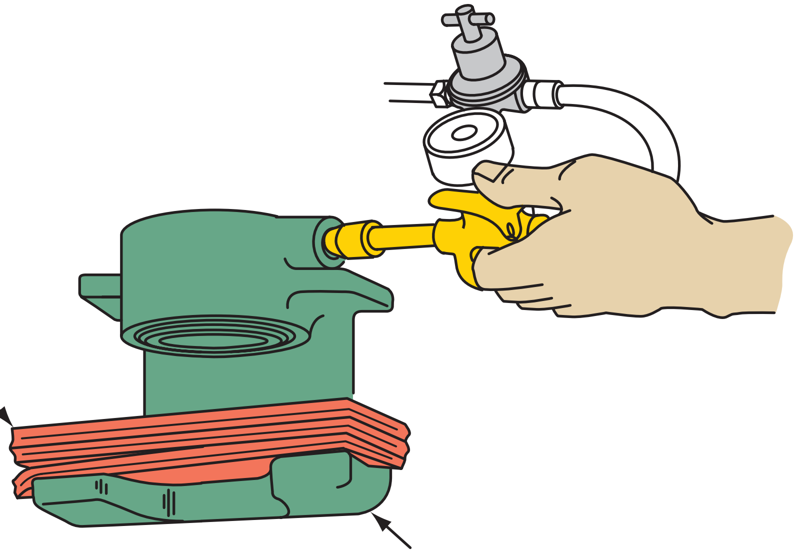

FIGURE 52-35 Using air to remove a piston.

If a piston is frozen, release air pressure and tap the piston into its bore with a soft-headed hammer or mallet. Reapply air pressure. Frozen phenolic (plastic) pistons can be broken into pieces with a chisel and hammer. Be careful not to damage the cylinder bore while doing this. Internal expanding pliers are sometimes used to remove pistons from caliper bores.

Inspect phenolic pistons for cracks, chips, or gouges. Replace the piston if any of these conditions are evident. If the plated surface of a steel piston is worn, pitted, scored, or corroded, it also should be replaced.

Dust boots vary in design depending on the type of piston and seal, but they all fit into one groove in the piston and another groove in the cylinder. One type comes out with the piston and peels off. Another type stays in place and the piston comes out through the boot, and then is removed from the cylinder **(Figure 52–36)**. In either case, peel the boot from its groove. In some cases it might be necessary to pry it out, but be careful not to scratch the cylinder bore while doing so. The old boot can be discarded since it must be replaced along with the seal.

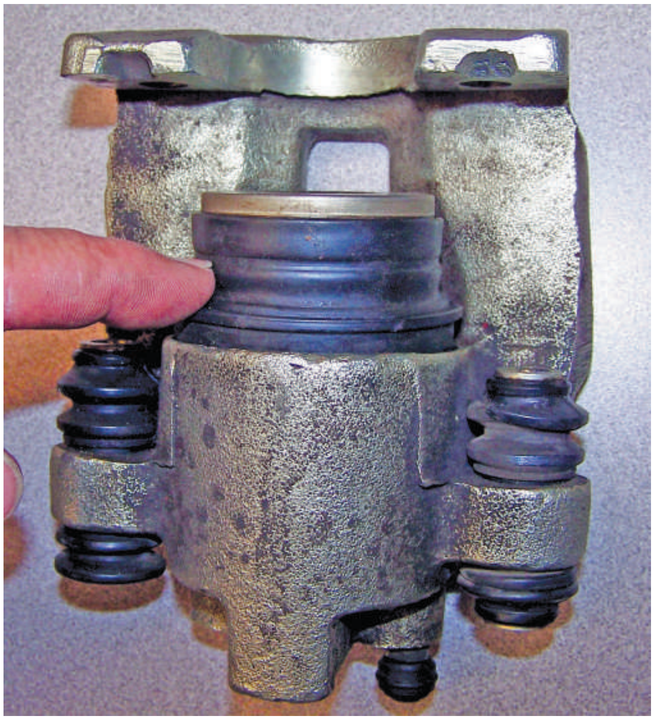

FIGURE 52-36 The dust boot is peeled away from the piston and caliper.

Remove the piston's and the cylinder's seal by prying them out with a wooden or plastic tool **(Figure 52–37)**. Do not use a screwdriver or other metal tool. Any of these could nick the metal in the caliper bore and cause a leak. Inspect the bore for pitting or scoring. A bore that shows light scratches or corrosion can usually be cleaned with crocus cloth. However, a bore that has deep scratches or scoring normally indicates that the caliper should be replaced. In some cases, the cylinder can be honed. Check the service information before doing this. If there is no mention of honing the bore, the manufacturer probably does not recommend it. Black stains on the bore walls are caused by piston seals. They do no harm.

When using a hone, be sure to install the hone baffle before honing the bore. The baffle protects the

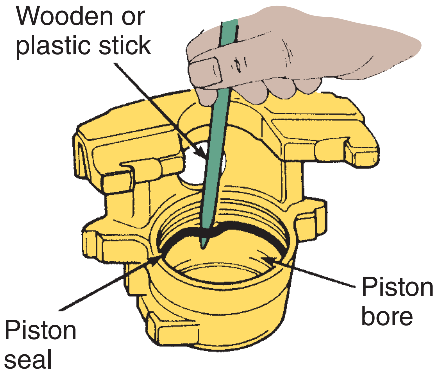

FIGURE 52-37 Removing a piston seal with a wooden or plastic stick.

hone stones from damage. Use extreme care in cleaning the caliper after honing. Remove all dust and grit by flushing the caliper with alcohol. Wipe it dry with a clean lint-free cloth and then clean the caliper a second time in the same manner.

Loaded Calipers

Rather than overhaul a caliper, many shops install loaded calipers. Loaded calipers are complete units with friction pads and mounting hardware included. Besides the convenience and the savings of installation time, preassembled calipers also reduce the odds of errors during caliper overhaul.

Mistakes that are frequently made when replacing calipers include forgetting to bend the pad locating tabs that prevent pad vibration and noise, leaving off antirattle clips and pad insulators, and reusing corroded caliper mounting hardware that can cause a floating caliper to bind up and wear the pads unevenly.

Caliper Reassembly

Before assembling the caliper, clean the phenolic piston (if so equipped) and all metal parts to be reused in clean denatured alcohol or brake fluid. Then, clean out and dry the grooves and passageways with compressed air. Make sure that the caliper bore and component parts are thoroughly clean.

To replace a typical piston seal, dust boot, and piston, first lubricate the new piston seal with clean brake fluid or assembly lubricant (usually supplied with the caliper rebuild kit). Make sure the seal is not distorted. Insert it into the groove in the cylinder bore so it does not become twisted or rolled. Install a new dust boot by setting the flange squarely in the outer groove of the caliper bore. Next, coat the piston with brake fluid or assembly lubricant and install it in the cylinder bore. Be sure to use a wood block or other flat stock when installing the piston back into the piston bore. Never apply a C-clamp directly to a phenolic piston, and be sure the pistons are not cocked. Spread the dust boot over the piston as it is installed. Seat the dust boot in the piston groove.

SHOP TALK

Avoid mismatching friction materials from side to side. When one caliper is bad, both calipers should be replaced using the same friction material.

With some types of boot/piston arrangements, the procedure for installation is slightly different from that already described. That is, the new dust boot is pulled over the end of the piston **(Figure 52–38)**. Lubricate the piston with brake fluid before installing it in the caliper. Then by hand, slip the piston carefully into the cylinder bore, pushing it straight, so the piston seal is not damaged during installation. Use an installation tool or wooden block to seat the new dust boot **(Figure 52–39)**.

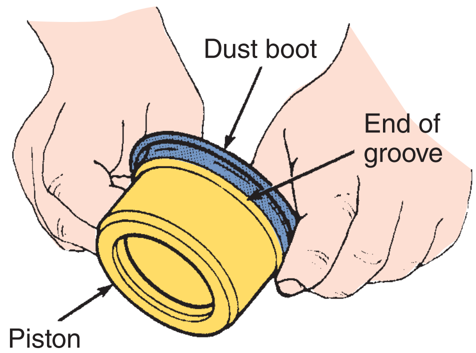

FIGURE 52-38 Some installation procedures require the dust boot to be pulled over the end of the piston.

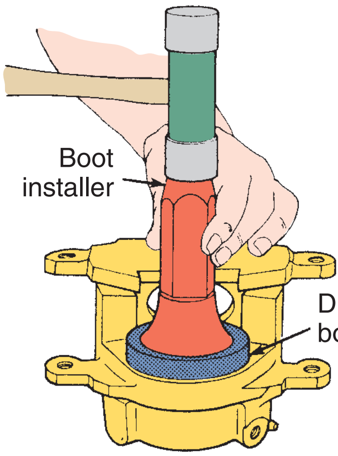

FIGURE 52-39 Seating a dust boot with a boot installer.

Caution! On fixed calipers, bridge bolts are used to hold the two caliper halves together. These are high-tensile bolts ordered only by specific part number. They require accurate torque tightness to prevent leakage. Do not attempt to use standard bolts in place of bridge bolts.

Another point to keep in mind is that some caliper designs have a slot cut in the face of the pistons that must align with an antisqueal shim. Make sure that the piston and shim align. It might be necessary to turn the piston to achieve proper alignment. To complete the caliper assembly job, install the bleeder screw.

Brake Pad Installation

It is a good practice to replace disc brake **hardware (Figure 52–40)** when replacing disc brake pads. The brake hardware typically consists of the guides, clips, and rubber parts used to hold and secure the pads and calipers. Replacement of the hardware ensures proper caliper movement and brake pad retention. It also aids in preventing brake noise and uneven brake pad wear.

One of the major causes of premature brake wear is rust. It causes improper slider and piston operation that leads to uneven pad wear. Tests have shown that when only the pads are replaced, the new pads can wear out in half the mileage they should if the calipers or slides are corroded. Therefore, if the calipers are corroded, replace them. You should always replace the pad guides. If the pads slide on a bracket that does not use replaceable guides, thoroughly clean the contact areas and lubricate as recommended in the service information.

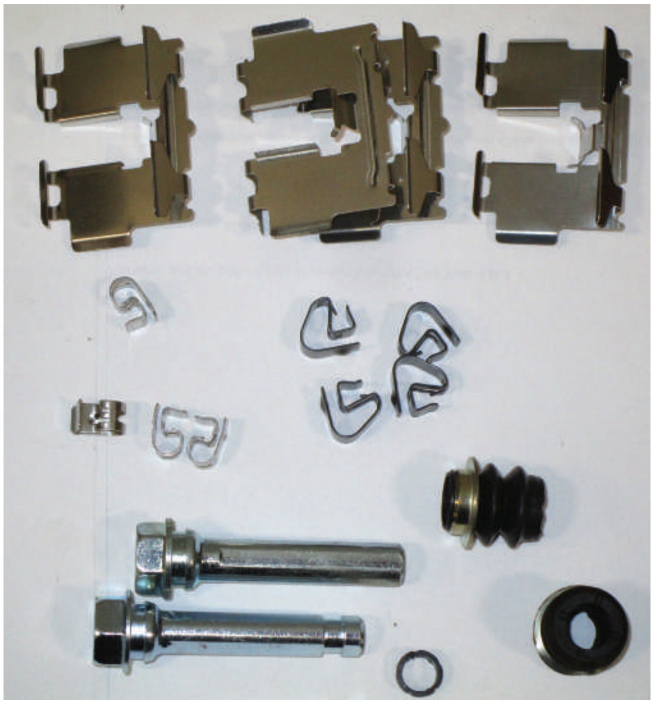

FIGURE 52–40 Replacement caliper hardware, pins, and bushings.

Fixed Caliper Brake Pads The designs of fixed caliper disc brakes vary slightly. Generally, to replace the pads, insert new pads and plates in the caliper with the metal plates against the end of the pistons. Be sure that the plates are properly seated in the caliper. Spread the pads apart and slide the caliper into position on the rotor. With some pads, mounting bolts are used to hold them in place. These bolts are usually tightened 80 to 90 ft.-lb (108 to 122 N-m). On some fixed disc brakes, the pads are held in place by retaining clips and/or retaining pins. Reinstall the antirattle spring/clips and other hardware (if so equipped).

Sliding Caliper Brake Pads Push the piston carefully back into the bore until it bottoms. Lightly lubricate the sliding surfaces of the caliper and the caliper anchor. Slide a new outer pad into the recess of the caliper. No free play between the brake pad flanges and caliper fingers should exist. If free play is found, remove the pad from the caliper and bend the flanges to eliminate all vertical free play. Install the pad.

Place the inner pad into position on the caliper anchor with the pad's flange on the machined sliding area. Fit the caliper over the rotor. Align the caliper to the anchor and slide it into position. Be careful not to pull the dust boot from its groove when the piston and boot slide over the inboard pad. Install the antirattle springs (if so equipped) on top of the retainer plate and tighten the retaining screws to specification.

On some calipers, especially those used as parking brakes, there is a notch or groove in the piston and a tab on the rear of the inner pad. During installation of the pad, the tab must fit into the groove in the piston **(Figure 52–41)**.

Floating Caliper Brake Pads For floating or pin caliper disc brakes, compress the flanges of the outer bushing in the caliper fingers and work them into position in the hole from the outer side of the caliper. Compress the flanges of the inner guide pin bushings and install them.

FIGURE 52–41 On some rear brake assemblies with rotating piston parking brake, there is a tab on the back of the pad that must line up with the groove in the piston.

Slide the new pad and lining assemblies into position in the adapter and caliper. Be sure that the metal portion of the pad is fully recessed in the caliper and adapter and that the proper pad is on the outer side of the caliper.

Hold the outer pad and carefully slide the caliper into position on the anchor and over the disc. Align the guide pin holes of the anchor with those of the inner and outer pads. Lightly lubricate and install the guide pins through the bushings, caliper, anchor, and inner and outer pads into the outer bushings in the caliper and antirattle spring.

When installing any type of caliper, follow these guidelines:

- Make sure the correct caliper is installed on the correct anchor plate. Also make sure that the bolts are tightened to specifications.
- Lubricate the rubber insulators (if so equipped) with silicone dielectric compound or as specified by the manufacturer.
- After the caliper assembly is in its mounting brackets, connect the brake hose to the caliper. If copper washers or gaskets are used, be sure to use new ones—the old ones might have taken a set and might not form a tight seal if reused. Torque the caliper hose bolt to specifications.
- Fill the master cylinder reservoirs and bleed the hydraulic system.
- Check for fluid leaks under maximum pedal pressure.
- Lower the vehicle and road test it.

Rear Disc Brake Calipers

Rear disc brake calipers with some type of parking brake mechanism have different inspection and overhaul procedures than front brake calipers.

Vehicles with electronic parking brake systems or hill-assist braking require special service. Before attempting to service the brakes on a vehicle equipped with either of these features, check the service information to understand how the system operates and how to properly service the brakes. Failure to follow the service procedures can cause serious damage to the brake calipers.

If the rear calipers have traditional parking brake cables and an electric motor that pulls the cables to apply the parking brake, retracting the piston is performed with tool to thread the piston back into the bore **(Figure 52–42)**.

To retract the piston on rear calipers with electrically driven pistons, a scan tool may be required to place the electronic parking brake into Service Mode. This retracts the parking brake motors and allows the piston to be retracted back into the caliper bore. Some vehicles can be placed into a special service mode without a scan tool to safely work on the rear brakes. An example of how to do this on Ford Fusion models is as follows:

1. Set the ignition to ON.
2. Press and hold the accelerator pedal and place the electric parking brake (EPB) switch to RELEASE. Continue to hold the pedal and EPB switch.
3. Set the ignition to OFF then to ON within 5 seconds. Continue to hold the accelerator pedal and EPB switch.
4. Set the ignition to OFF then release the accelerator pedal and EPB switch.

Once the brake service has been completed, take the vehicle out of Service Mode. To do this, complete the following steps:

1. Set the ignition to ON.
2. Press and hold the accelerator pedal and place the EPB switch to APPLY. Continue to hold the accelerator pedal and EPB switch.
3. Set the ignition to OFF then to ON within 5 seconds. Continue to hold the accelerator pedal and EPB switch.
4. Release the accelerator pedal and EPB switch.

This will fully apply the parking brake and set the air gap between the pads and rotors. Always refer to

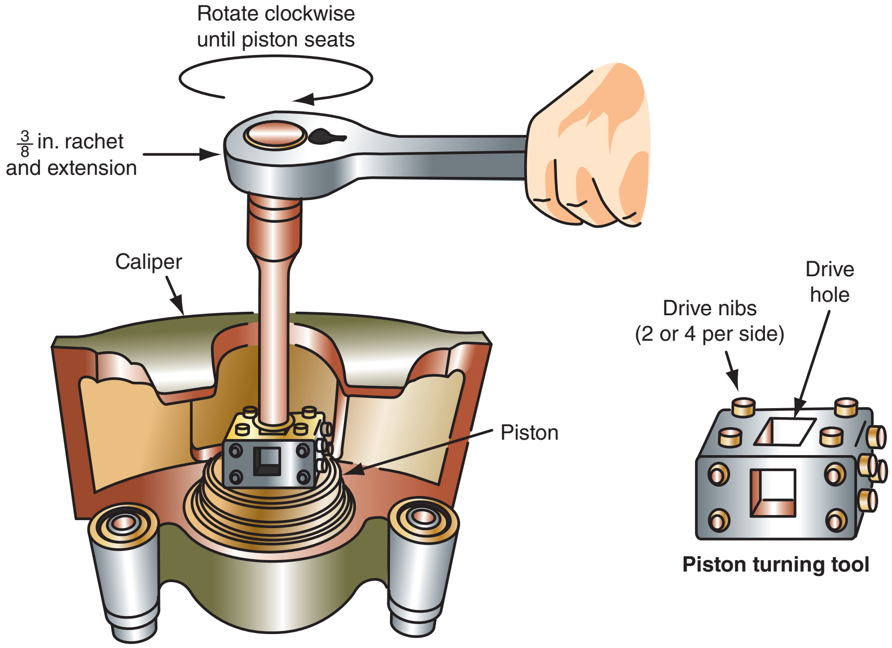

FIGURE 52–42 Using the tool to retract the caliper piston back into its bore.

the manufacturer's service information when working on any electronic parking brake or hill-assist system for specific procedures to prevent damage to the components.

Rotor Inspection

The rotors should be inspected whenever brake pads are replaced and when the wheels are removed for other services. They should be carefully checked to determine if they can be reused or machined or if they should be replaced. When inspecting the rotor, make sure you look at the sensor wheel for the wheel-speed sensor, if installed **(Figure 52–43)**.

If a good look at the surface is impossible because of dirt, clean the surfaces with a shop cloth dampened in brake cleaning solvent or alcohol. If the surface is rusted, remove it with medium-grit sandpaper or emery cloth and then clean it with brake cleaner or alcohol.

Most brake rotors have a discard thickness dimension cast into them. If you cannot find this dimension on the rotor or if it is hard to read, check the service information for thickness specifications. Rotor discard thickness dimensions are given in two or three decimal points (hundredths or thousandths of an inch or hundredths of a millimeter), such as 1.25 inches, 1.375 inches, 0.750 inch, or 24.75 mm. If you resurface the rotor, it must be 0.015 to 0.030 inch (0.38 to 0.76 mm) thicker than the discard dimension after machining to allow for wear. If a rotor is already below the minimal thickness spec, replace it. It is always wise to replace both rotors on the same axle.

FIGURE 52–43 Check the wheel-speed sensor's rotor when servicing a brake rotor.

SHOP TALK

Cross-drilled or slotted brake rotors may not be able to be machined. Therefore, if the rotor is scored or otherwise damaged, it should be replaced.

PROCEDURE

To overhaul a typical rear wheel caliper when there is no auxiliary drum parking brake follow these steps:

STEP 1 Unbolt the caliper.

STEP 2 Disconnect the parking brake cable from the lever on the caliper.

STEP 3 Disconnect the brake hose from the caliper, remove the caliper mounting bolts, and lift the caliper off its support.

STEP 4 Remove the brake pads and all pad shims and retainers.

STEP 5 Remove the piston from its bore; this procedure will vary based on the type of caliper being serviced. When the piston is free, remove the piston boot.

STEP 6 Carefully inspect the piston for wear. Replace the piston if it is worn or damaged in any way.

STEP 7 Remove the piston seal from the caliper using the tip of a screwdriver or a wooden or plastic scraper, being careful not to scratch the bore.

STEP 8 Service of the remaining internal components will vary depending on the caliper. Refer to the manufacturers' service information.

STEP 9 Coat the new piston seal and piston boot with silicone grease and install them in the caliper.

STEP 10 Coat the outside of the piston with brake fluid and install it on the adjusting bolt while rotating it clockwise with the locknut wrench.

STEP 11 Install the new brake pads, pad shims, retainers, and springs onto the caliper bracket.

STEP 12 Reinstall the caliper and the splash shield and tighten the caliper bolts to torque specifications.

STEP 13 Reconnect the brake hose to the caliper with new sealing washers and tighten the banjo bolt to specifications.

STEP 14 Then reconnect the parking brake cable to the arm on the caliper and reinstall the caliper shield.

STEP 15 Top off the master cylinder reservoir and bleed the brake system. Adjust the parking brake as needed. Before making adjustments, be sure the parking brake arm on the caliper touches the pin.

New rotors come with a protective coating on the friction surfaces. To remove this coating, use brake cleaner, or the solvent recommended by the manufacturer.

Thickness and Parallelism

To measure rotor thickness, place a brake disc micrometer about 1 inch in from the outer edge of the rotor and measure the thickness **(Figure 52–44).** Compare the measurement to specifications. Repeat the measurement at about eight points equidistant (45 degrees) around the surface of the rotor and compare each measurement to specifications. Take all measurements at the same distance from the edge so that rotor taper does not affect the measurements. If the rotor is thinner than the minimum thickness at any point or if thickness variations exceed limits, it must be replaced. Also check the service information for an allowable thickness variation. Many manufacturers hold

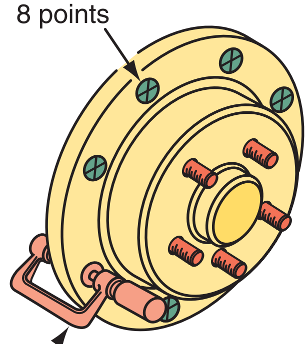

FIGURE 52–44 To check a rotor's thickness and parallelism, measure the rotor at eight different spots.

tolerances on thickness variations as close as 0.0005 inch (0.013 mm).

Rotor **parallelism** refers to thickness variations in the rotor from one measurement point to another around the rotor surface. If the rotor is out of parallel, it can cause excessive pedal travel; front end vibration; pedal pulsation; chatter; and, on occasion, grabbing of the brakes. The rotor then must be resurfaced or replaced.

Lateral Runout

Excessive lateral runout is the wobbling of a rotor from side to side when it rotates **(Figure 52–45)**. This wobble knocks the pads farther back than normal, causing the pedal to pulse and vibrate during braking. Over time, runout can cause excessive parallelism. This occurs as the rotor rubs against the pads as it rotates, wearing away at the rotor and causing it to become thinner in certain sections. Chatter can also result. Lateral runout also causes excessive pedal travel because the pistons have farther to travel to reach the rotor. If runout exceeds specifications, the rotor must be turned or replaced.

For the best braking performance, lateral runout should be less than 0.003 inch (0.08 mm) for most vehicles. Some manufacturers, however, specify runout limits as small as 0.002 inch (0.05 mm) or as great as 0.008 inch (0.20 mm).

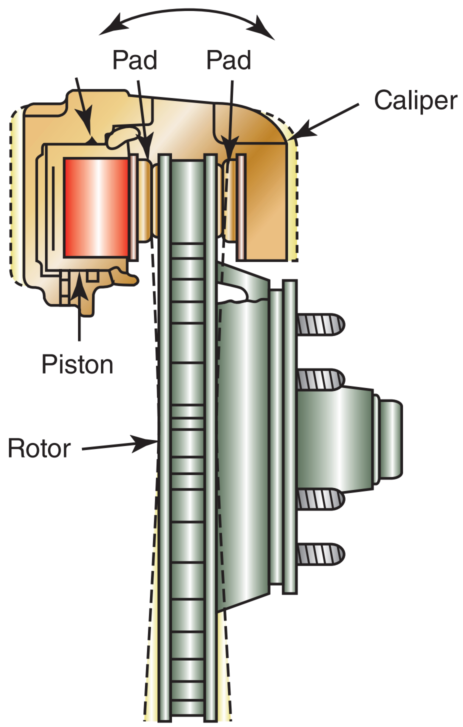

FIGURE 52–45 Excessive lateral runout causes the rotor to wobble from side to side when it rotates.

Runout measurements are taken only on the outboard surface of the rotor, using a dial indicator and suitable mounting adapters **(Figure 52–46)**. If the rotor is mounted on adjustable wheel bearings, readjust the bearings to remove bearing end play. Do not overtighten the bearings. On rotors bolted solidly to the axles of FWD vehicles, bearing end play is not a factor in rotor runout measurement. If there is excessive bearing end play, the bearing assembly must be replaced. Bearing end play is best checked with a dial indicator.

Clamp the dial indicator support to the steering knuckle or other suspension part that will hold it securely as you turn the rotor. Position the dial indicator so that its tip contacts the rotor at 90 degrees. Place the indicator tip on the friction surface about 1 inch in from the outer edge of the rotor. Do not place the dial indicator on a dirty, rusted, grooved, or scored area. Rotate the rotor until the lowest reading appears on the dial indicator; then set the indicator to zero. Turn the rotor through one complete revolution and compare the lowest to the highest reading. This is the maximum runout of the rotor.

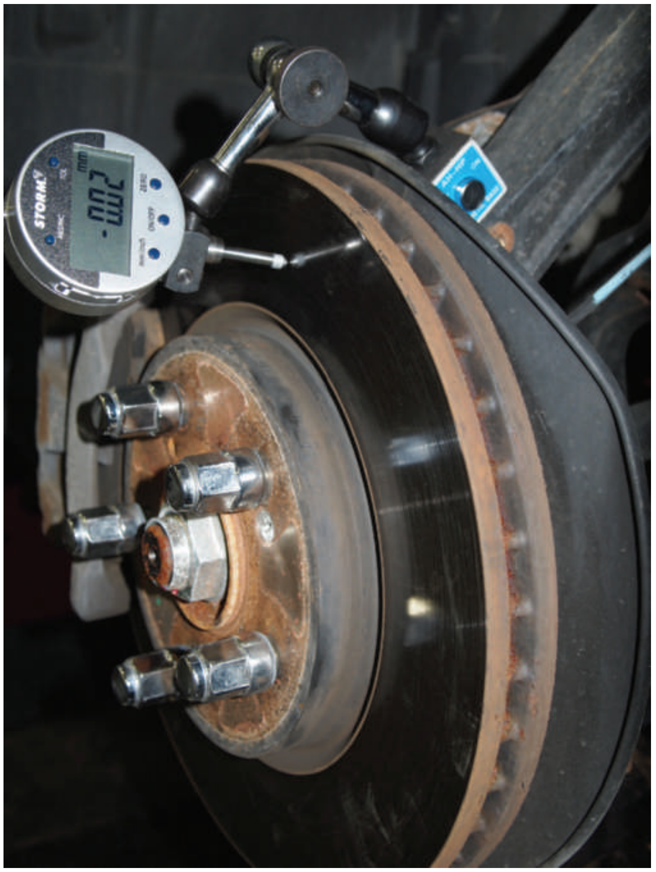

FIGURE 52–46 Runout measurements are taken on the outboard surface of the rotor, using a dial indicator and suitable mounting adapters.

Additional Checks

The following are some of the typical rotor conditions that warrant disc replacement or machining.

Grooves and Scoring Inspect both rotor surfaces for scoring and grooving. Scoring or small grooves up to 0.010 inch (0.25 mm) deep are usually acceptable for proper braking performance. Scoring can be caused by linings that are worn through to the rivets or backing plate or by friction material that is harsh or unkind to the mating surface. Rust, road dirt, and other contamination could also cause rotor scoring. Any rotor having score marks more than 0.15 inch should be refinished or replaced **(Figure 52–47)**.

If the rotor is deeply grooved, it must be thick enough to allow the grooves to be completely removed without machining the rotor to less than its minimum thickness. Measure rotor thickness at the bottom of the deepest groove. If rotor thickness at the bottom of the deepest grooves is at or near the discard dimension, replace the rotor.

Cracks Check the rotor thoroughly for cracks or broken edges. Replace any rotor that is cracked or chipped, but do not mistake small surface checks in the rotor for structural cracks. Surface checks will normally disappear when a rotor is resurfaced. Structural cracks, however, will be more visible when surrounded by a freshly turned rotor surface.

SHOP TALK

Some older rotors, particularly on GM vehicles, have a single deep groove manufactured into each surface. This groove helps to keep the pads from moving outward and also reduces operating noise.

FIGURE 52-47 Any rotor having score marks more than 0.15 inch deep should be refinished or replaced.

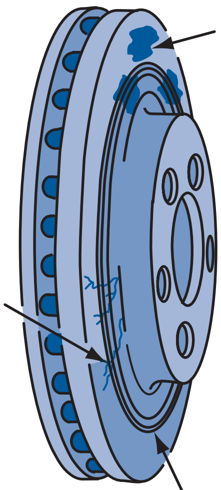

FIGURE 52-48 Some of the typical conditions that should be looked for on a brake rotor.

Bluing or Heat Checking Inspect the rotor surfaces for heat checking and hard spots **(Figure 52–48)**. Heat checking appears as many small interlaced cracks on the surface. Heat checking lowers the heat dissipation ability and friction coefficient of the rotor surface. Heat checking does not disappear with resurfacing. Therefore, a rotor with heat checks should be replaced.

Hard spots appear as round, shiny, bluish areas on the friction surface. Hard spots on the surface of a rotor usually results from a change in the metallurgy caused by brake heat. Pulling, rapid wear, hard pedal, and noise occur. These spots can be removed by machining. However, only the raised surfaces are removed, and they could reappear when heat is again encountered. The rotor should be replaced.

Rust If the vehicle has not been driven for a period of time, the discs will rust in the area not covered by the lining and cause noise and chatter. This also can result in excessive wear and scoring of the discs and pads. Wear ridges on the discs can cause temporary improper pad contact if the ridges are not removed before the installation of new pads. Rusted rotors should be cleaned before any measurements are taken.

Inspect the fins of vented rotors for cracks and rust. Rust near the fins can cause the rotor to expand and lead to rotor thickness variations and excessive runout

FIGURE 52-49 A severely rusted brake rotor, obviously this should be replaced.

problems. Machining the rotor may remove runout and thickness variations, but rotor expansion due to rust may cause these problems to reappear soon. Rusted rotors should be replaced **(Figure 52–49)**.

Rotor Service

If the thickness of the rotor is below or close to the minimal allowable thickness or is badly distorted, it must be replaced. If the thickness is greater than the minimum specifications, it can be trued and smoothened with a brake lathe. Rotors that have minor imperfections or are slightly unparallel can be turned true and smooth with a brake lathe.

Removing a Rotor

To remove a rotor, raise the vehicle and remove the wheel. Then remove the caliper from the rotor and suspend it with wire from the suspension of the vehicle. Before you remove a rotor, mark it "L" or "R" for left or right so that it gets reinstalled on the same side of the vehicle from which it was removed. If the rotors have not been off before, make an index mark on the rotor to a wheel stud or hub so that the rotor can be reinstalled in the same position on the hub.

If the rotor is a floating rotor, remove it from the hub by pulling it off the hub studs. If you cannot pull the rotor off by hand, apply penetrating oil on the front and rear rotor-to-hub mating surfaces. Strike the rotor between the studs using a ball-peen hammer. If this does not free the rotor, attach a three-jaw puller to the rotor and pull it off.

Whenever you separate a floating rotor from the hub flange, clean any rust or dirt from the mating surfaces of the hub and rotor. Neglecting to clean rust and dirt from the rotor and hub mounting surfaces before installing the rotor will result in increased rotor lateral runout, leading to premature brake pulsation and other problems.

If the rotor and hub are a one-piece assembly, remove the outer wheel bearing and lift the rotor and hub off the spindle. Some rotors, such as that shown in **Figure 52–50**, are bolted to the hub and bearing assembly and can only be removed by removing the hub unit. Once removed, the rotor is unbolted from the hub **(Figure 52–51)**.

FIGURE 52-50 Some rotors are bolted to the hub and bearing assembly and can only be removed by removing the hub unit.

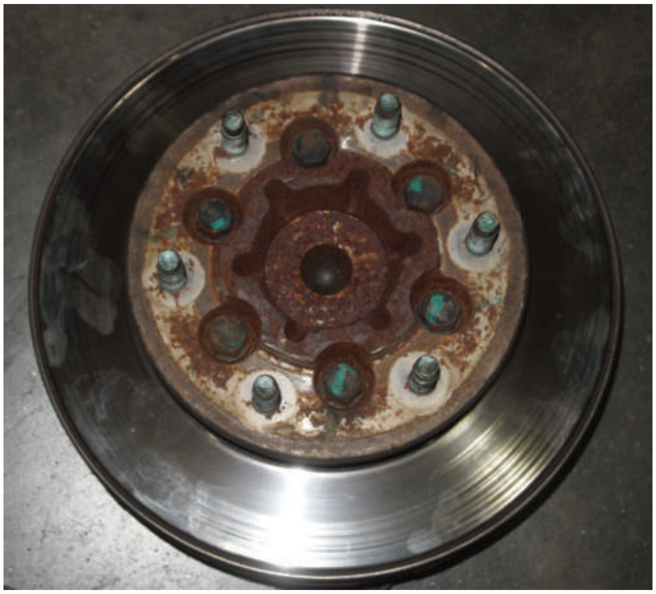

FIGURE 52-51 Once the hub unit and rotor are removed, the rotor can be unbolted from the hub.

SHOP TALK

New rotors have the correct surface finish, which may be disturbed by them turning on a lathe. Clean any oil film off a new rotor with brake cleaning solvent or alcohol and let the rotor air dry before installing it on the vehicle.

Caution! Do not attempt to use a brake lathe without proper training. You can be seriously injured if the lathe is not properly set up or is operated improperly.

FIGURE 52–52 A typical bench lathe.

Brake Lathes

A brake lathe cuts metal away to achieve the desired surface finish. There are basically two types of brake disc lathes used by the industry. The first one, a bench brake lathe, has the capability of resurfacing brake drums and brake discs after they have been removed from the vehicle. The lathe rotates the disc as cutting tools work their way across the braking surface of the disc. The second type is an on-vehicle brake lathe. This type of brake lathe is a time saver because the rotor does not need to be removed from the vehicle. Special fixtures are used to straddle the rotor so the cutting tools can precisely cut both sides of the rotor. An electric motor is used to rotate the disc and hub assembly during cutting. On-car lathes have become the standard for refinishing front brake rotors due to their ability to compensate for any runout in the front hub assembly.

Whenever you refinish a rotor, remove the least amount of metal possible to achieve the proper finish. This helps to ensure the longest service life from the rotor. Never turn the rotor on one side of the vehicle without turning the rotor on the other side. Left- and right-side rotors should be the same thickness, generally within 0.002 inch to 0.003 inch. Similarly, equal amounts of metal should be cut off both surfaces of a rotor.

Bench Lathes On a bench, off-vehicle lathe, the rotor is mounted on the lathe's arbor and turned at a controlled speed while a cutting bit passes across the rotor surface to remove a few thousandths of an inch of metal **(Figure 52–52)**. The lathe turns the rotor perpendicularly to the cutting bits so that the entire rotor surface is refinished. Most rotor cutting assemblies have two cutting bits. The rotor mounts between the bits and is pinched between them. As the cut is made, the same amount of surface material should be cut from both sides of the rotor.

When using a bench lathe, clean the rotor's hub and mounting surfaces before mounting the rotor on the lathe. This helps reduce any runout caused by improper setup. Select the correct mounting adaptors and secure the rotor on the lathe. Start the lathe and check for rotor runout; remount the rotor as needed. Install the vibration dampers and position the cutting head over the rotor and perform a scratch cut to check rotor setup. Make a slight cut on both sides of the rotor then remount it 180 degrees from the starting point and make another slight cut. The two cuts should be parallel, indicating the rotor is mounted correctly. If the cuts are 180 degrees apart, there is runout in the mounting setup that needs to be corrected before machining.

Once properly setup, perform a fast cut to clean and true the surfaces. Inspect the rotor once the cut is complete. If the surface is clean and true, perform a slow cut. The slow cut machines the rotor to the correct surface roughness. Once complete, apply a nondirectional finish **(Figure 52–53)** to break up the radial lines caused by machining. Wash the rotor in warm soapy water, dry completely, and measure the final thickness.

On-Vehicle Brake Lathes The advantage of an on-vehicle lathe **(Figure 52–54)** is that the rotor does not need to be removed. On-vehicle lathes also are ideal for rotors with excessive runout problems.

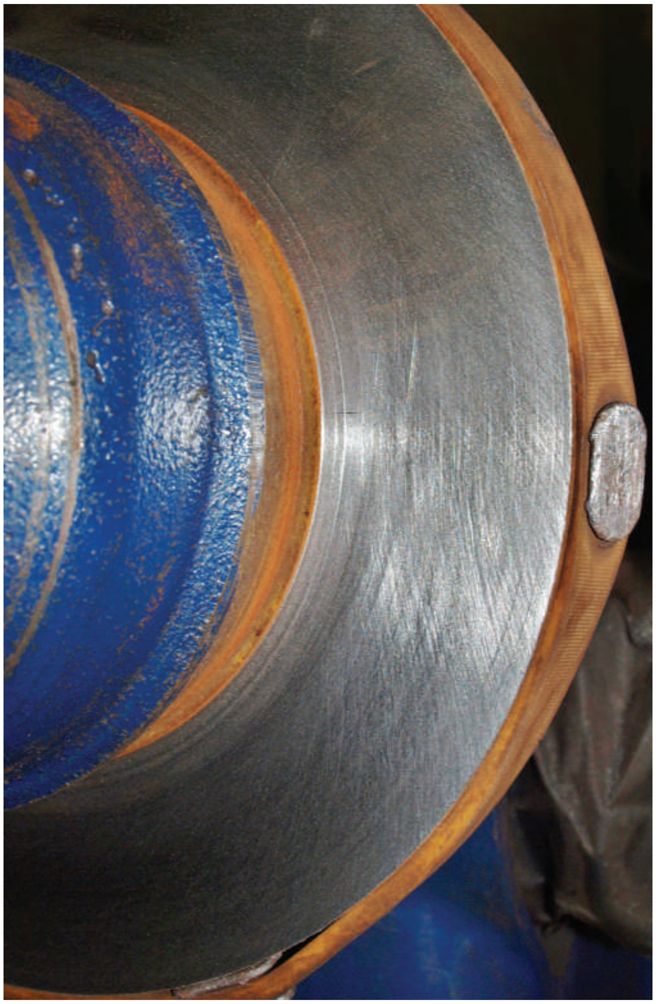

FIGURE 52-53 A non-directional finish.

FIGURE 52-54 An on-vehicle brake lathe.

To install the lathe, remove the wheel and then remove the caliper. If any end play is present in an adjustable tapered roller bearing, carefully tighten the adjusting nut by hand just enough to remove the end play before installing the lathe. After turning the rotor, readjust the bearing.

Select the correct mounting adaptor to fit the lug pattern and install it onto the hub. Do not overtighten the mounting nuts. Position the lathe to the adaptor and secure it in place. Make sure the lathe and adaptor are properly aligned to prevent damage to either. Next, move the cutting head to fit over the rotor and adjust it into place.

Before machining begins, compensate the lathe for runout. On some models this is a manual adjustment. Most common lathes have automatic compensation. Follow the manufacturer's operating instructions for runout compensation. Improper setup and compensation can increase runout in the rotor, causing you to lose time and money.

Once the lathe is setup and compensated, proceed to machine the rotor. Remove only as much material as is needed to true the rotor. Some on-car lathes require only one pass over the rotor so separate fast and slow cuts are not needed. After machining, remeasure rotor thickness and check it against specifications. Dismount the lathe and mark the rotor's location on the hub. Remove and clean the rotor with warm soapy water and dry completely. Reinstall the rotor and brakes, torquing all fasteners to specifications.

Installing a Rotor

If the rotor is a floating rotor, make sure all mounting surfaces are clean. Apply a small amount of antiseize compound to the pilot diameter of the disc brake rotor before installing the rotor on the hub. Reinstall the caliper. If the rotor is a fixed rotor, one-piece assembly with the hub that contains the wheel bearings, clean and repack the bearings and install the rotor.

Install the wheel and tire on the rotor and torque the wheel nuts to specifications, following the recommended tightening pattern. Failure to tighten in the correct pattern may result in increased lateral runout, brake roughness, or pulsation as well as damage to the wheels.

Final Checks and Pad Break-In

After lowering the vehicle to the ground, pump the brake pedal several times before moving the vehicle. This positions the brake linings against the rotor and ensures that the brake pedal pumps up and is firm under pressure. Typically, four-wheel disc brake equipped vehicles have a firm, high, brake pedal with minimal travel before the brakes apply. Vehicles with disc/drum systems may have

slightly more pedal travel depending on the rear shoe adjustment.

Verify that the brake fluid level is correct in the master cylinder, and then test-drive the vehicle. During the test-drive, note the feel of the brake pedal and listen for any noise when braking.

Follow the brake pad manufacturer's recommendations for breaking-in or bedding-in the pads before returning the vehicle to the customer. The break-in process is important so the pads deposit a layer of material onto the rotors. The following are examples of pad break-in procedures:

- Make approximately 20 normal stops from 30 mph.
- Make approximately 20 slow-downs from 50 to 20 mph.
- Make five moderate stops from 40 to 10 mph without letting the breaks cool.

Caution! When working on vehicles with carbon ceramic brake rotors, use guide pins to properly locate the wheels during installation **(Figure 52–55)**. Carbon ceramic rotors are brittle and can be chipped when reinstalling the wheel. With these rotors costing up to $4,000 a piece, use caution and care when working around them.

FIGURE 52–55 Wheel locating pins help prevent damage to ceramic rotors.

The break-in procedure will vary with pad manufacturer and type of pad. It is important to follow the pad manufacturer's instructions to achieve the correct contact between the pads and the rotors. Proper break-in will reduce noise and vibration and prolong the life of the pads.

SUMMARY

- Disc brakes offer four major advantages over drum brakes: resistance to heat fade, resistance to water fade, increased straight-line stopping ability, and automatic adjustment.
- The typical rotor is attached to and rotates with the wheel hub assembly. Heavier vehicles generally use ventilated rotors. Splash shields protect the rotors and pads from road moisture and dirt.
- The caliper assembly includes cylinder bores and pistons, dust boots, and piston hydraulic seals.
- Brake pads are placed in each side of the caliper and together straddle the rotor. Some brake pads have wear sensors.
- Fixed caliper disc brakes do not move when the brakes are applied. Floating caliper disc brakes slide back and forth on pins or bolts. Sliding calipers slide on surfaces that have been machined smooth for this purpose.
- In a rear disc brake system the inside of each rear wheel hub and rotor assembly is used as the parking brake drum.
- Rear disc parking brakes have a mechanism that forces the pads against the rotor mechanically.
- The general procedures involved in a complete caliper overhaul include tasks such as: caliper removal, brake pad removal, caliper disassembly, caliper assembly, brake pad installation, and caliper installation.
- The first step in proper caliper service is to remove the caliper assembly from the vehicle.
- Disc brake pads should be checked periodically or whenever the wheels are removed. They should be replaced if they fail to exceed minimum lining thickness as listed in the service information.
- To disassemble the caliper, the piston and dust boot must first be removed. Compressed air is used to pop the piston out of the bore.
- Before assembling the caliper, all metal parts and the phenolic piston are cleaned in denatured alcohol or brake fluid. The grooves and passageways of the caliper are cleaned out and dried with compressed air.
- It is a good practice to replace disc brake hardware when replacing disc brake pads.
- Disc brake rotor conditions that must be corrected include lateral runout, lack of parallelism, scoring, blueing or heat checking, and rusty rotors.

ANTILOCK BRAKE, TRACTION CONTROL, AND STABILITY CONTROL SYSTEMS

CHAPTER 53

OBJECTIVES

- Explain how antilock brake systems work to bring a vehicle to a controlled stop.
- Describe the differences between an integrated and a nonintegrated antilock brake system.
- Describe the operation of the major components of an antilock brake system.
- Describe the operation of the major components of automatic traction and stability control systems.
- Explain the best procedure for finding ABS faults.
- List the precautions that should be followed whenever working on an antilock brake system.

Antilock brake systems (ABS) and traction and electronic stability control (ESC) systems, once expensive options, are now standard equipment on all passenger cars and light-duty vehicles. These systems add yet another group of electronically controlled systems to the increasingly complex modern vehicle. For example, under the umbrella of ABS and ESC are often other systems such as electronic brake force distribution, traction control, hill start assist, supplemental braking, adaptive cruise control, and collision avoidance.

Antilock Brakes

Modern antilock brake systems **(Figure 53–1)** can be thought of as electronic/hydraulic pumping of the brakes for straight-line stopping under panic conditions. Good drivers have always pumped the brake pedal during panic stops to avoid wheel lockup and the loss of steering control. Antilock brake systems simply get the pumping job done much faster and in

a much more precise manner than the fastest human foot. Keep in mind that a tire on the verge of slipping produces more friction with respect to the road than one that is locked and skidding. Once a tire loses its grip, friction is reduced, control is compromised, and the vehicle takes longer to stop.

Pressure Modulation

When the driver quickly and firmly applies the brakes and holds the pedal down, the brakes of a vehicle not equipped with ABS will almost immediately lock the wheels. The vehicle slides rather than rolls to a stop. During this time, the driver also has a very difficult time keeping the vehicle straight and the vehicle can skid out of control. The skidding and lack of control was caused by the locking of the wheels. If the driver was able to release the brake pedal just before the wheels locked up then reapply the brakes, the skidding could be avoided.

This release and apply of the brake pedal is exactly what an antilock system does. When the brake pedal is pumped or pulsed, pressure is quickly applied and released at the wheels. This is called **pressure modulation**. Pressure modulation works to prevent wheel locking. Antilock brake systems can modulate the pressure to the brakes as often as fifteen times per second. By modulating the pressure to the brakes, friction between the tires and the road is maintained and the vehicle is able to come to a controllable stop.

Because the ABS is already controlling system pressure, most modern systems can control the hydraulic pressure to the wheel brakes in place of the metering and proportioning valves used on non-ABS systems. Electronic brake force distribution (EBD) is used to maintain balance between the front and rear brakes by monitoring the rear wheel speeds during braking. If the rear wheels slow down more quickly than the front wheels, the ABS can limit pressure to the rear while allowing pressure to the front brakes to build as needed.

The only time reduced friction aids in braking is when a tire is on loose snow. A locked tire allows a small wedge of snow to build up ahead of it, which allows it to stop in a shorter distance than a rolling tire.

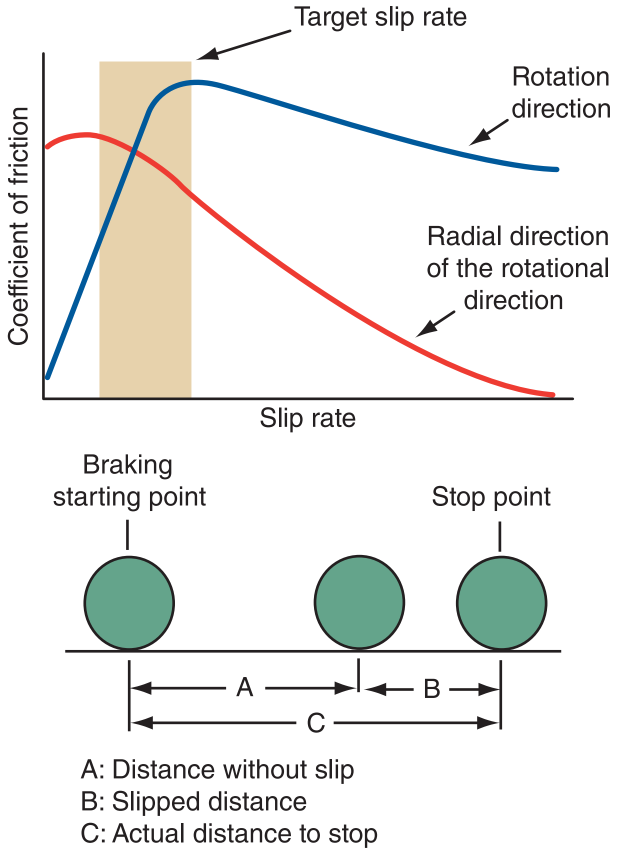
Steering is another important consideration. As long as a tire does not slip, it goes only in the direction in which it is turned. But once it skids, it has little or no directional stability. One of the big advantages of ABS, therefore, is the ability to keep control of the vehicle under all conditions.

Slip Rate

The maneuverability of the vehicle is reduced if the front wheels are locked, and the stability of the vehicle is reduced if the rear wheels are locked. A locked

tire skids on pavement and has poor traction. This condition allows for 100 percent tire slip, whereas a tire rolling freely has a slip of nearly 0 percent. Slip is the difference between the actual speed of the vehicle and the speed of the tire's tread as it rotates on the pavement. Antilock brake systems control the slip rate **(Figure 53–2)** of the wheels to ensure maximum grip force, or traction, at the tires. It is the traction of the tires that actually stops the vehicle; therefore, ABS can improve braking and handling by controlling the brake fluid pressure at each wheel to attain the target slip rate at that wheel.

Although ABS prevents complete wheel lockup, it allows some wheel slip in order to achieve the best braking possible. During ABS operation, the target slip rate can be from 10 to 30 percent. A slip rate of 25 percent means the velocity of a wheel is 25 percent less than that of a free rolling wheel at the same vehicle speed. Many things are considered when determining the target slip rate for a particular vehicle. For some the range is very low—5 to 10 percent—while on others it is high—20 to 30 percent.



$$\textbf{Slip rate} = \frac{B}{C} = \frac{\text{Vehicle speed} - \text{Wheel speed}}{\text{Vehicle speed}}$$

FIGURE 53–2 Defining slip rate.

CUSTOMER CARE

Remind your customers that pumping the brake pedal while stopping will prevent the ABS from activating. They should always keep firm steady pressure on the brake pedal during braking.

Pedal Feel

The brake pedal on a vehicle equipped with ABS has a different feel than that of a conventional braking system. When the ABS is activated, a small bump followed by rapid pedal pulsations will continue until the vehicle comes to a stop or the ABS turns off. These pulsations are the result of the modulation of pressure to the brakes and are felt more on some systems than on others. This is due to the use of damping valves in some modulation units. If pedal feel is of concern during diagnosis of a brake problem, compare the brake pedal feel with that of a similar vehicle with a normal operating antilock brake system. With ABS, the brake pedal effort and pedal feel during normal braking are similar to that of a conventional power brake system.

ABS Components

Many different designs of antilock brake systems are found on today's vehicles. These designs vary in their basic layout, operation, and components. There are also variations based on the type of power-assist used. Systems that combine ABS and power assist functions are called integral systems. The ABS components that may be found on a vehicle can be divided into two categories: hydraulic and electrical/electronic components. Keep in mind that no one system uses all of the parts discussed here. Normal or conventional brake parts are part of the overall brake system but are not in the following discussion.

Hydraulic Components

Accumulator An accumulator is used to store hydraulic fluid to maintain high pressure in the brake system and to provide residual pressure for power-assisted braking. Normally, the accumulator is charged with nitrogen gas **(Figure 53–3)** and is an integral part of the modulator unit. This unit is typically found on vehicles with a hydraulically assisted brake system.

FIGURE 53-3 Pressure in an accumulator.

FIGURE 53-5 A master brake cylinder in this typical integrated system uses an electric pump for power boost.

Antilock Hydraulic Control Valve Assembly This assembly controls the release and application of brake system pressure to the wheel brake assemblies. It may be of the integral type, meaning this unit is combined with the power-boost and master cylinder units into one assembly **(Figure 53–4)**. The nonintegral type is mounted externally from the master cylinder/power booster unit and is located between the master cylinder and wheel brake assemblies. Both types generally contain solenoid valves that control the releasing, the holding, and the applying of brake system pressure.

Booster Pump The booster pump is an assembly of an electric motor and pump. The booster pump is used to provide pressurized hydraulic fluid for the ABS. The pump's motor is controlled by the system's control unit. The booster pump is also called the electric pump and motor assembly.

Booster/Master Cylinder Assembly The booster/master cylinder assembly **(Figure 53–5)**, sometimes referred to as the hydraulic unit, contains the valves and pistons needed to modulate hydraulic pressure in the wheel circuits during ABS operation. Power brake-assist is provided by pressurized brake fluid supplied by a hydraulic pump.

Fluid Accumulators Different than a pressure accumulator, fluid accumulators temporarily store brake fluid removed from the wheel brake units during an ABS cycle. This fluid is then used by the pump to build pressure for the brake hydraulic system. There are normally two fluid accumulators in a hydraulic control unit, one each for the primary and secondary hydraulic circuits.

Hydraulic Control Unit This assembly contains the solenoid valves, fluid accumulators, pump, and an

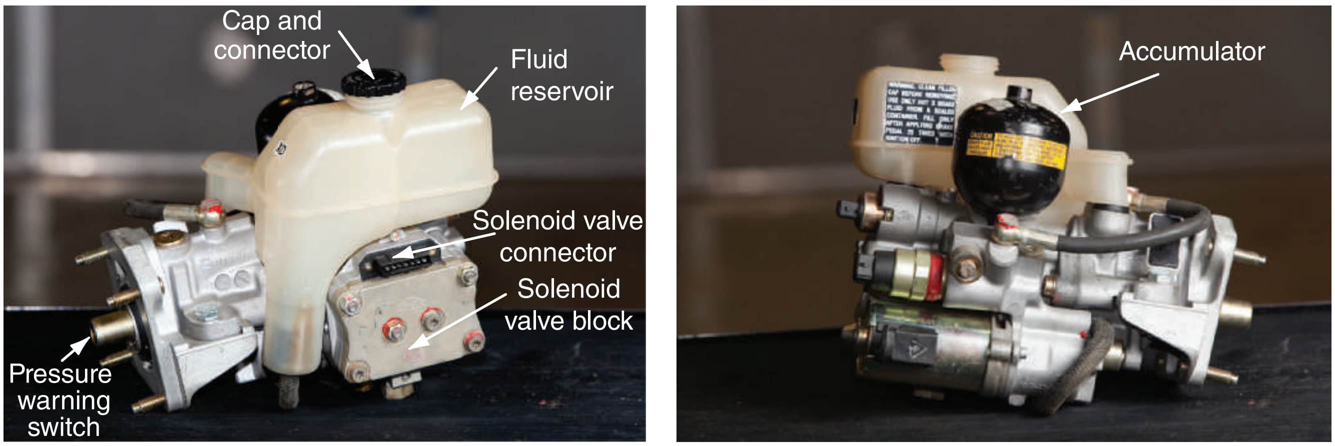

FIGURE 53-4 An integrated ABS combines the master cylinder, brake booster, and ABS components in a single unit.

electric motor. This is actually a combination unit of many individual components found separately in some systems. The unit may have one pump and one motor or it will have one motor and two pumps: one pump for half of the hydraulic system and the other for the other half.

Main Valve This two-position valve is also controlled by the ABS control module and is open only in the ABS mode. When open, pressurized brake fluid from the booster circuit is directed into the master cylinder (front brake) circuits to prevent excessive pedal travel.

Modulator Unit The modulator unit **(Figure 53–6)** controls the flow of pressurized brake fluid to the individual wheel circuits. Normally the modulator is made up of solenoids that open and close valves, several valves that control the flow of fluid to the wheel brake units, and electrical relays that activate or deactivate the solenoids through the commands of the control module. This unit may also be called the hydraulic actuator, hydraulic power unit, or the electrohydraulic control valve.

Solenoid Valves The solenoid valves are located in the modulator unit and are electrically operated by signals from the control module. The control module switches the solenoids on or off to increase, decrease, or maintain the hydraulic pressure to the individual wheel units.

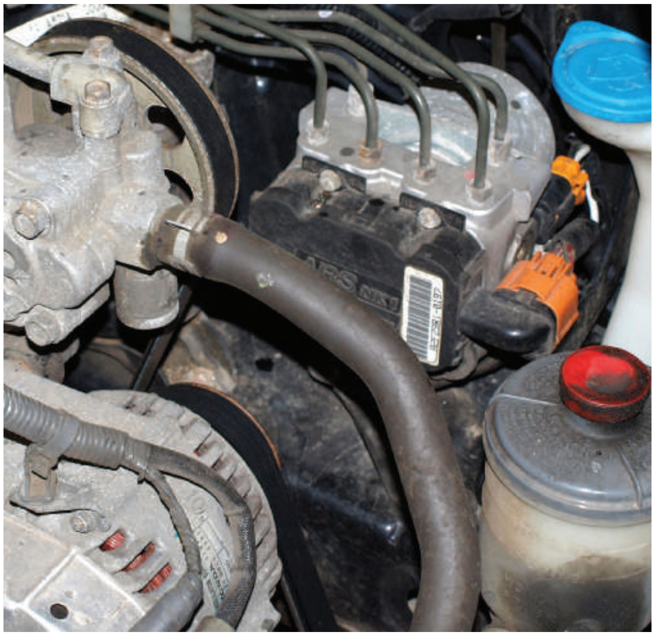

FIGURE 53–6 An ABS modulator assembly.

Valve Block Assembly The valve block assembly attaches to the side of the booster/master cylinder and contains the hydraulic wheel circuit solenoid valves **(Figure 53–7)**. The control module controls the position of these solenoid valves. The valve block is serviceable separate from the booster/master cylinder but should not be disassembled. An electrical connector links the valve block to the ABS control module.

Wheel Circuit Valves Two solenoid valves are used to control each circuit or channel. One controls the inlet valve of the circuit, the other controls the outlet valve. When inlet and outlet valves of a circuit are used in combination, pressure can be increased, decreased, or held steady in the circuit. The position of each valve is determined by the control module. Outlet valves are normally closed, and inlet valves are normally open. Valves are activated when the ABS control module switches 12 volts to the circuit solenoids. During normal driving, the circuits are not activated.

Electrical/Electronic Components

ABS Control Module This small control computer is normally mounted to the master cylinder **(Figure 53–8)**, or is part of the hydraulic control unit. It monitors system operation and controls antilock function when

FIGURE 53–7 The valve block assembly attaches to the side of the booster/master cylinder and contains the hydraulic wheel circuit solenoid valves.

needed. The module relies on inputs from the wheel-speed sensors and feedback from the hydraulic unit to determine if the antilock brake system is operating correctly and to determine when the antilock mode is required. The module has a self-diagnostic function including numerous trouble codes. This module may also be called the ECU (electronic control unit), EBCM (electronic brake control module), the antilock brake controller, or the ECM (electronic control module). The name used depends on the manufacturer and year of the vehicle. Regardless of the name used, the control module may control ABS, ESC, and many other related systems.

Data Link Connector (DLC). The DLC provides access and/or control of vehicle information, operating conditions, and diagnostic information.

Diagnostic Trouble Code (DTC). These trouble codes are numeric identifiers for fault conditions identified by the ABS's internal diagnostic system.

Brake Pedal Position Sensor The antilock brake pedal position sensor is used by the ABS module to determine when the brake pedal is pressed, how far or how hard the pedal is pressed. The BPP sensor input is used by the ABS, ESC, the engine control module, transmission control module, cruise control, and others.

Indicator Lights Most ABS-equipped vehicles are fitted with two different brake warning lights. One of the warning lights is tied directly to the ABS, whereas the other lamp is part of the base brake system. All vehicles have a *red* warning light. This lamp lights when the brake fluid level is low, when there is a problem with the brake system, or when the parking brake is on. An *amber* warning lamp lights when there is a fault in the ABS. Both lamps will illuminate if there is a major problem in the base system, causing the ABS to be inhibited **(Figure 53–9)**.

Lateral Acceleration/Longitudinal/Yaw Sensors Used on vehicles with stability control, these sensors monitor the sideward movement, forward/rearward motion, and movement around the center of vehicle's axis. These sensors may be part of the restraint system and the data can be shared with the ABS and ESC. Data from these sensors may be used to ensure proper braking during turns, to keep the vehicle stable in corners, and for torque vectoring to improve stability and performance.

Pressure Switch This switch controls pump motor operation and the low pressure warning light circuit. The pressure switch grounds the pump motor relay coil circuit, activating the pump when accumulator pressure drops below 2,030 psi (14,000 kPa). The switch cuts off the motor when the pressure reaches 2,610 psi (18,000 kPa). The pressure switch also contains switches to activate the dash-mounted warning light if accumulator pressure drops below 1,500 psi (10,343 kPa). This unit is typically found on vehicles with a hydraulically assisted brake system.

Pressure Differential Switch The pressure differential switch is located in the modulator unit. This switch sends a signal to the control module whenever there is an undesirable difference in hydraulic pressures within the brake system.

Relays Relays are electromagnetic devices used to control a high-current circuit with a low-current switching circuit. In ABS, relays are used to switch motors and solenoids. A low-current signal from the control module energizes the relays that complete the electrical circuit for the motor or solenoid.

Toothed Ring The toothed ring, also called a tone or reluctor ring, can be located on an axle shaft, differential gear, or a wheel's hub. This ring is used in conjunction with the wheel-speed sensor. The ring has a number of teeth around its circumference. The number of teeth varies by manufacturer and vehicle model. As the ring rotates and each tooth passes by the wheel-speed sensor, an AC voltage signal is generated between the sensor and the tooth. As the tooth moves away from the sensor, the signal is broken until the next tooth comes close to the sensor. The end result is a pulsing signal that is sent to the control module. The control module translates the signal into wheel speed. The toothed ring may also be called the reluctor, tone ring, or gear pulser.

Wheel-Speed Sensor

The wheel-speed sensors (WSS) **(Figure 53–10)** are mounted near the different toothed rings. Two types of sensors are in use: passive sensors, which generate AC voltage signals, and active sensors, which generate digital DC signals. As the ring's teeth rotate past the sensor, an AC voltage is generated. As the teeth move away from the sensor, the signal is broken until the next tooth comes close to the sensor. The end result is a pulsing signal that is sent to the control module **(Figure 53–11)**. The control module translates the signal into wheel speed. The sensor is normally a small coil of wire with a permanent magnet (PM) in its center.

Active sensors may have two or three wires and are either Hall-effect or magnetoresistive sensors that produce a square-wave digital signal **(Figure 53–12)**. Active sensors are now commonly used because unlike PM sensors, digital sensors can be used down to zero mph and can determine the direction the wheel is turning. This is necessary for electronic

stability system operation as well as vehicles with hill assist takeoff.

Multiplexing

The electronic circuit and wiring of an ABS is tied into the vehicle's CAN network **(Figure 53–13)**. This allows the ABS control unit to communicate with other control modules and share input devices with them. CAN communications is especially important when ABS is modified with additional features, such as traction and stability control.

Basic Operation

The control unit processes inputs and controls the operation of **isolation/dump valves** in the hydraulic modulator unit. The isolation/dump valves block off or isolate the master cylinder from certain brakes. As long as the brakes are applied and the vehicle is moving, the master cylinder remains isolated so additional fluid cannot be directed to those brakes. At the same time, the dump valve opens and allows a very small amount of fluid from the brake lines to enter an accumulator **(Figure 53–14)**. This reduces

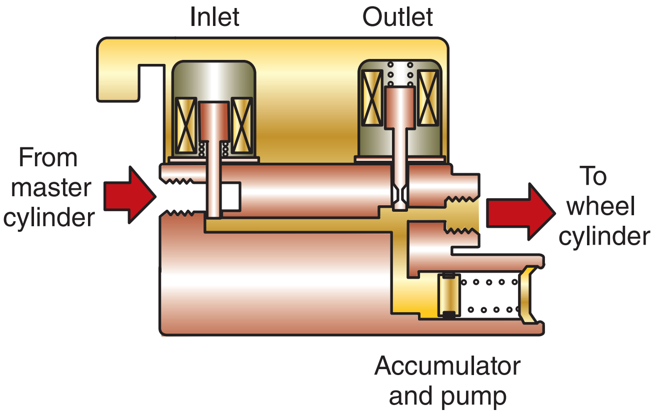

FIGURE 53–14 The control unit processes inputs and controls the operation of the isolation/dump valves to block off or isolate the master cylinder from the brakes.

the hydraulic pressure delivered to the brake and it is slightly released to allow the wheels to turn. If the wheels speed up too much, the dump valve reverses and the accumulator forces a small amount of fluid back into the brake. This constant dump/recharge is what causes the pulsation of the brake pedal during a panic or ABS stop. Most systems have a dedicated isolation/dump valve for each wheel.

Types of Antilock Brake Systems

The ABSs found on today's vehicles are manufactured by one of many different companies. Each manufacturer has a unique way to accomplish the same thing—vehicle control during braking. When working with ABS, it is important that you identify the exact system you are working with and follow the specific service procedures for that system. Often the system is initially identified by the manufacturer and then its model number; for example, a Teves Mark 20 system was manufactured by Teves and this model 20 is found on 1997 and later Chrysler vehicles. Keep in mind that there have been nearly 50 different ABSs used by the industry in recent years.

The exact manner in which hydraulic pressure is controlled depends on the ABS design. Many of the earlier ABSs were integrated or **integral antilock brake systems**. They combine the master cylinder, hydraulic booster, and ABS hydraulic circuitry into a single hydraulic assembly. These systems are becoming more prevalent because of the increasing number of hybrid and electric vehicles on the market. Integral systems use electric pumps instead of vacuum boosters to supply assist.

Nearly all of today's systems on non-hybrid vehicles are **nonintegral antilock brake systems**. They use a conventional vacuum-assist booster and master cylinder. The ABS hydraulic control unit is a separate mechanism. In some nonintegrated systems, the master cylinder supplies brake fluid to the hydraulic unit. Although the hydraulic unit is a separate assembly, it still uses a high-pressure pump/motor, an accumulator, and fast-acting solenoid valves to control hydraulic pressure to the wheels.

Both integral and nonintegral systems operate in much the same way; therefore, an understanding of one system will lend itself to the understanding of the other systems.

General Motors' electromagnetic ABS is a different type of nonintegral system that uses a conventional vacuum power booster and master brake cylinder. But it does not use a high-pressure pump/motor, an accumulator, and fast-acting solenoid valves to control hydraulic pressure. Instead, it uses motors in a hydraulic modulator.

In addition to being classified as integral and nonintegral ABSs, systems can be broken down into the level of control they provide. ABSs can be one-, two-, three-, or four-channel, two- or four-wheel systems. A channel is merely a hydraulic circuit to the brakes.

Two-Wheel Systems

These basic systems offer antilock brake performance to the rear wheels only. They do not provide antilock performance to the steering wheels. Two-wheel systems are most often found on older light trucks and some sport utility vehicles **(Figure 53–15)**.

These systems can be either one- or two-channel systems. In one-channel systems, the rear brakes on both sides of the vehicle are modulated at the same time to control skidding. These systems rely on the input from a centrally located speed sensor. The speed sensor is normally positioned on the ring gear in the differential unit **(Figure 53–16)**, transmission, or transfer case.

Two-channel systems may be found on some diagonally split brake systems. These systems use two speed sensors to provide wheel speed data for the regulation of all four wheels. One sensor has input that controls the right front wheel; the other sensor performs identically for the left front wheel.

Brake hydraulic pressure to the opposite rear wheel is controlled simultaneously with its diagonally located front wheel. For example, the right rear wheel receives the same pumping instructions as the left front wheel. This system is an upgrade from

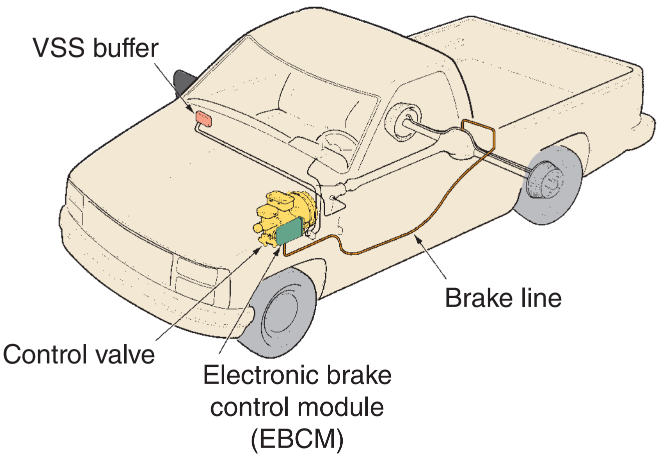

FIGURE 53–15 The main components of a rear wheel ABS.

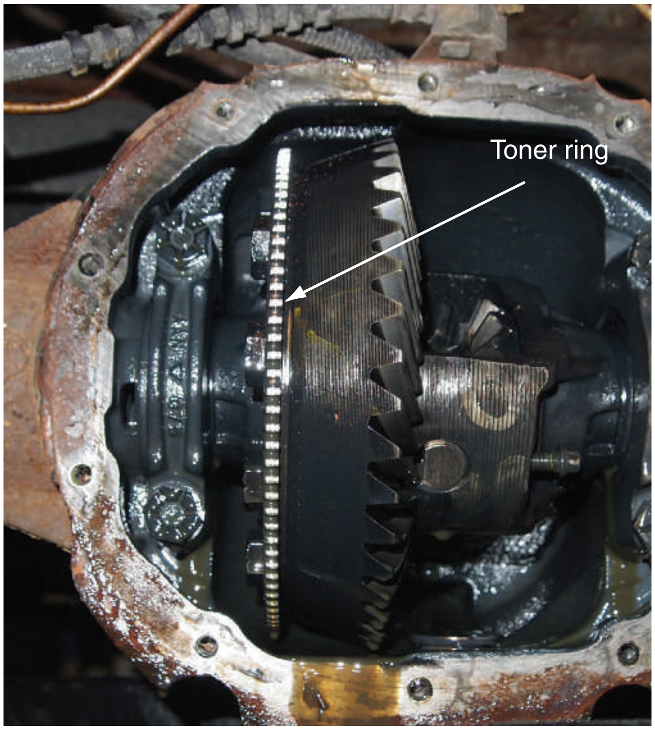

FIGURE 53–16 The speed sensor for both rear wheels is located on the differential unit.

the two-wheel system since it does provide steering control. However, it can have shortcomings under certain operating conditions.

Full (Four-Wheel) Systems

Some hydraulic systems that are split from front to rear use a three-channel system and are called four-wheel antilock brake systems. These systems have individual hydraulic circuits to each of the two front wheels, and a single circuit to the two rear wheels.

The most effective and most common ABSs are four-channel systems, in which sensors monitor each of the four wheels. With this continuous information, the ABS control module ensures that each wheel receives the exact braking force it needs to maintain both antilock and steering control.

ABS Operation

The exact operation of an antilock brake system depends on its design and manufacturer. It would take many pages to try to explain the operation of each, and as soon as you read the explanations there would be two or more new systems that would have to be explained. The exact operation of any system can be easily understood if you understand the basic operation of a few. The primary difference in operation between them all is based on the components used by the system. Therefore, the following systems were chosen as examples of how certain systems operate with the components they have.

Two-Wheel Systems (Nonintegral)

These systems are used to prevent rear wheel lockup on older pickup trucks and SUVs, especially under light payload conditions. They consist of a standard power brake system, an electronic control unit (control module), and an isolation/dump valve assembly. The valve assembly is attached to the master cylinder at the rear brake line. Both rear wheel brake assemblies are controlled by the valve assembly under ABS conditions.

Under normal braking, pressure will pass through the valve assembly. If the control module detects a deceleration rate from the VSS that would indicate probable rear wheel lockup, it activates the isolation valve, which stops the buildup of pressure to the rear wheels. If further deceleration occurs that would indicate lockup, the control module will rapidly pulse the dump valve to release brake pressure into the accumulator. The control module continues to pulse the dump valve until rear wheel deceleration matches the vehicle's deceleration rate or the desired slip rate. When wheel-speed picks up, the control module will turn off the isolation valve, allowing the fluid in the accumulator to return to the master cylinder and normal braking control to resume.

The control module continuously monitors the speed of the differential ring gear through signals from the rear wheel-speed sensor. The control module also receives signals from the brake light switch, brake warning lamp switch, reset switch, and the 4WD switch.

This system is disabled on four-wheel drive vehicles when in the four-wheel drive mode due to transfer case operation. Switching the transfer case into two-wheel drive mode will re-enable the ABS.

Four-Wheel Systems (Nonintegral)

The hydraulic circuit for this system is an independent four-channel type **(Figure 53–17)**. The hydraulic control unit is a separate unit. In the hydraulic control unit there are two valves per wheel; therefore, a total of eight valves are used. Some systems have three channels, one for each of the front wheels and one for the rear axle. Obviously these systems have only three pairs of solenoids **(Figure 53–18)**.

The system prevents wheel lockup during an emergency stop by modulating brake pressure. It

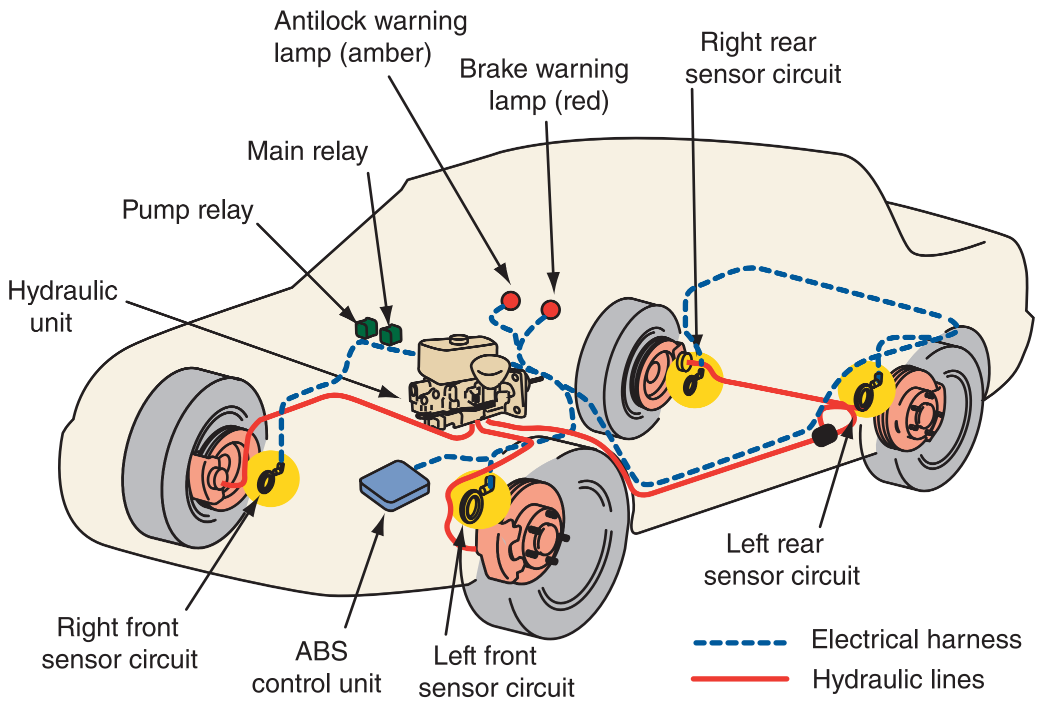

FIGURE 53–17 The basic electrical and hydraulic components of a four-wheel antilock brake system.

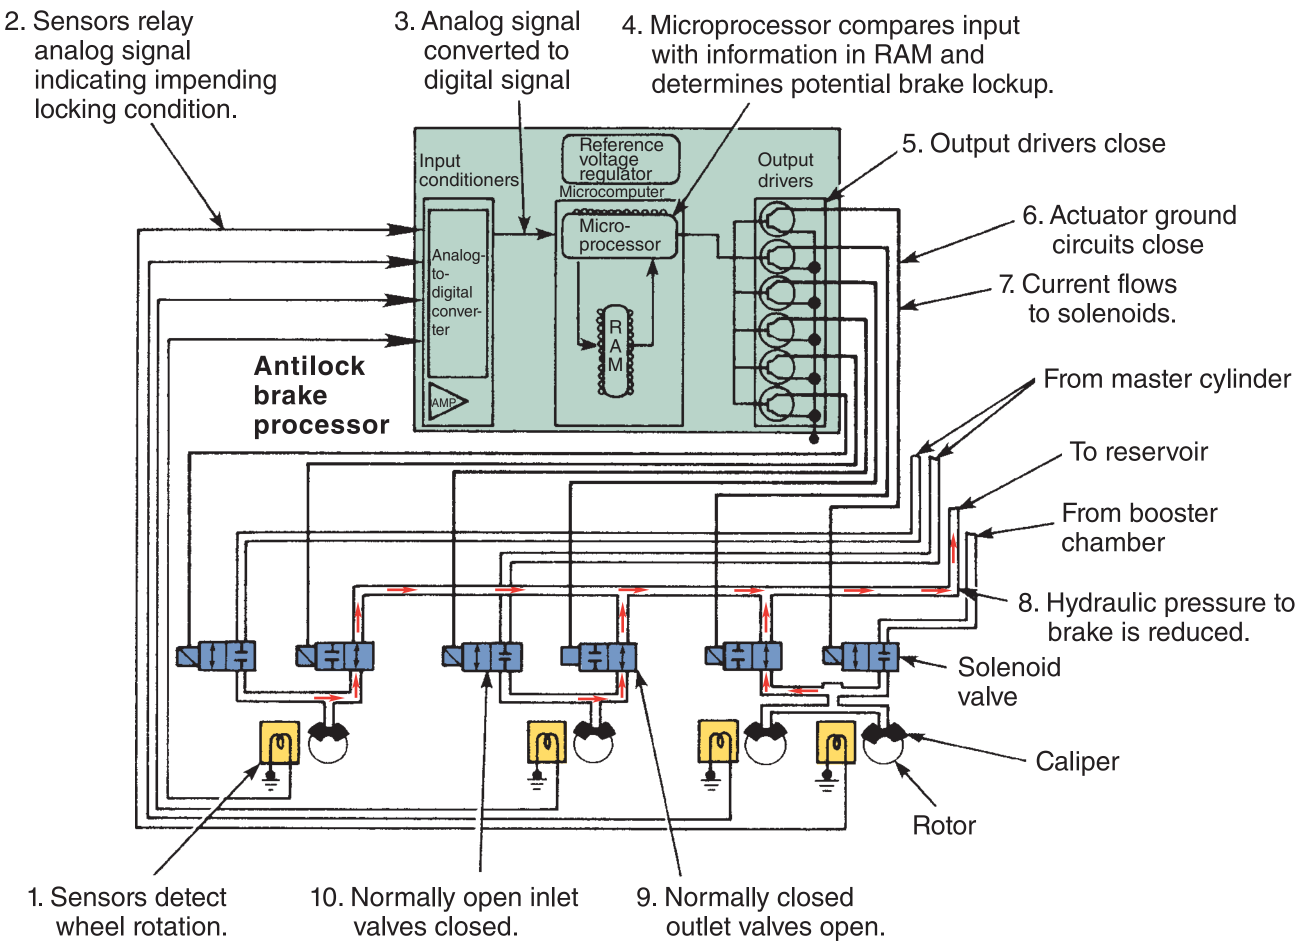

FIGURE 53–18 ABS operation—potential brake lock condition.

allows the driver to maintain steering control and stop the vehicle in the shortest possible distance under most conditions. During ABS operation, the driver will sense a pulsation in the brake pedal and a clicking sound.

Operation The ABS control module calculates the slip rate of the wheels and controls the brake fluid pressure to certain wheel brakes to reach the target slip rate. If the control module senses that a wheel is about to lock, based on input sensor data, it pulses the normally open inlet solenoid valve closed for that circuit. This prevents any more fluid from entering that circuit. The ABS control module then looks at the sensor signal from the affected wheel again. If that wheel is still decelerating faster than the other three wheels, it opens the normally closed outlet solenoid valve for that circuit. This dumps any pressure that is trapped between the closed inlet valve and the brake back to the master cylinder reservoir. Once the affected wheel returns to the same speed as the other wheels, the control module returns the valves to their normal condition, allowing fluid flow to the affected brake.

Wheel speed at each wheel is measured by the wheel-speed sensors (WSS). As the teeth on the gear pulser or tone wheel rotate past the sensor, a signal is generated. The frequency changes in accordance with the wheel speed.

Modulator Assembly The ABS modulator assembly consists of the inlet solenoid valve, outlet solenoid valve, reservoir, pump, pump motor, and the damping chamber. The hydraulic control has three modes: pressure reduction (decrease), pressure retaining (hold), and pressure intensifying (increase).

While in the pressure reduction decrease mode **(Figure 53–19)**, the inlet valve is closed and the outlet valve is open. During this mode, fluid pressure to the wheel brake is blocked and the existing fluid in the

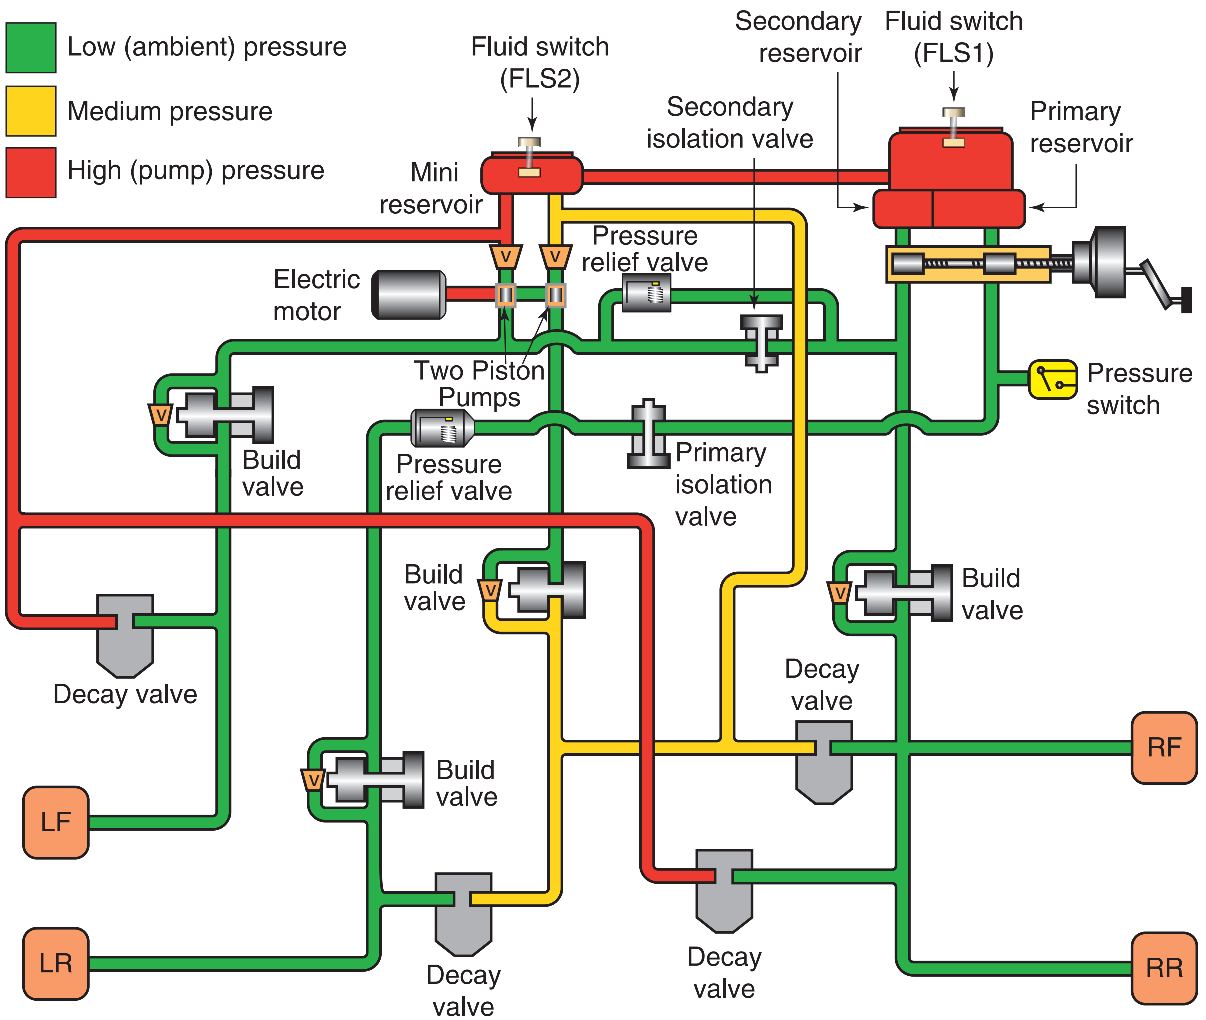

FIGURE 53–19 Antilock braking, pressure reduction.

caliper flows through the outlet valve back to the master cylinder reservoir. During the pressure-intensifying mode **(Figure 53–20)**, the inlet valve is open and the outlet valve is closed. Pressurized fluid is pumped to the caliper. To keep the pressure at the caliper during the pressure-retaining mode, the inlet and outlet valves are closed.

The pump/motor provides the extra fluid required during an ABS stop. The pump is supplied fluid that is released to the accumulators when the outlet valve is open during an ABS stop. The accumulators provide temporary fluid storage for use during an ABS stop. The pump also drains the accumulator circuits after the ABS stop is complete. The pump is run by an electric motor controlled by a relay that is controlled by the ABS control module. The pump is continuously on during an ABS stop and remains on for about 5 seconds after the stop is complete.

Keep in mind that the activity of the solenoid valves changes rapidly, several times each second. This means the fluid under pressure must be redirected quickly; this is the primary job of the pump.

Integral Four-Wheel Systems

When the brakes are released, the piston in the master cylinder retracts. The booster chamber is vented to the reservoir, and the fluid in the chamber is at the same low pressure as the reservoir. When the brakes are applied, under normal conditions, the brake pedal actuates a pushrod **(Figure 53–21)**. This moves a lever, which moves a spool valve. When the spool valve moves, it closes the port from the booster chamber to the reservoir and partially opens the port from the accumulator in proportion to the pressure on the brake pedal. This allows hydraulic fluid under pressure from the accumulator to enter the booster chamber. As hydraulic pressure enters, it pushes the booster piston forward, providing hydraulic assist to the mechanical thrust from the pushrod.

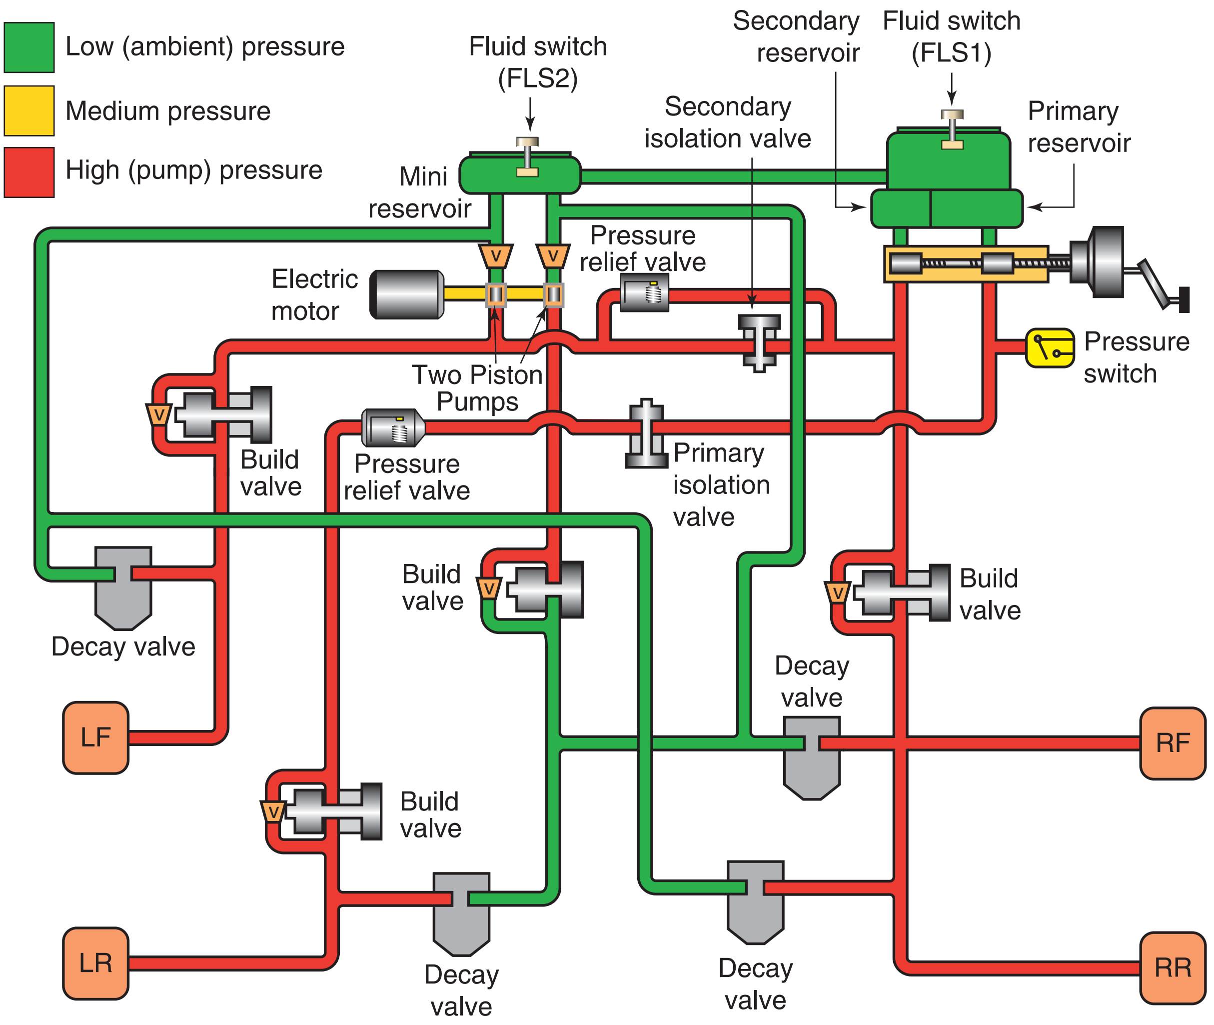

FIGURE 53-20 Antilock braking, pressure increase.

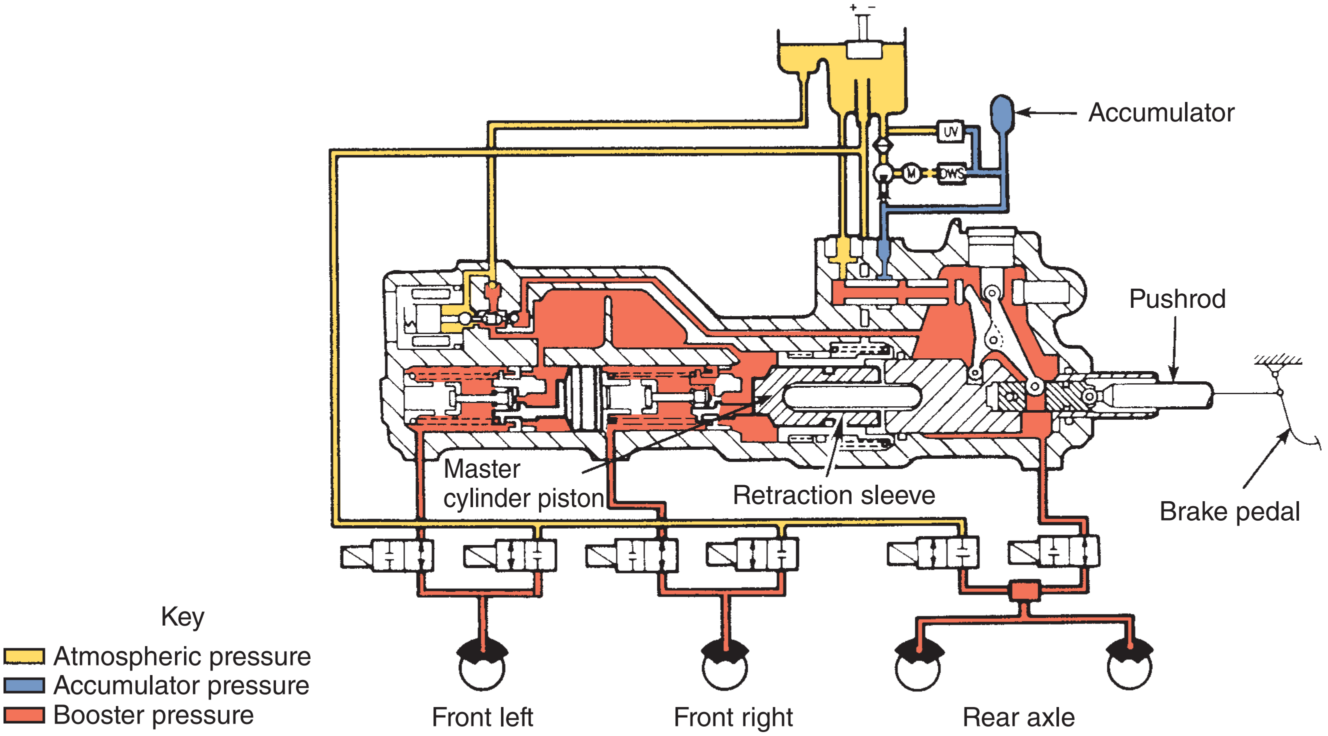

FIGURE 53–21 Normal braking with antilock system.

When the control module determines that the wheels are locking up, it opens a valve that supplies one chamber between the two master cylinder pistons and another chamber between the retraction sleeve and the first master cylinder piston. The hydraulic pressure on the retraction sleeve retracts the pushrod, pushing back the brake pedal. In effect, the hydraulic pressure to the wheels is now supplied by the accumulator, not by the brake pedal action. The control module also opens and closes the solenoid valves to cycle the brakes on the wheels that have been locking up.

When the solenoid valves are open, the master cylinder pistons supply hydraulic fluid to the front brakes, and the boost pressure chamber provides hydraulic pressure to the rear. When the solenoid valves are closed, the hydraulic fluid from the master cylinder pistons and booster pressure chamber is cut off. The hydraulic fluid is returned from the brakes to the reservoir.

Adaptive Braking

Many modern automobiles are now equipped with electronic brake-assist systems that can prepare or apply the brakes based on operating conditions. Some vehicles apply the brakes slightly when driving in rain or wet conditions. This keeps the pads and rotors dry and more responsive when applied.

Many systems can determine if an emergency braking event is occurring with input from forward-facing cameras and/or radar signals from the adaptive cruise control system. Each manufacturer has a different name for their system but all use forward-facing detection systems to determine if an obstacle is in the path of the vehicle. During low-speed driving, the system can precharge the brakes, keeping the pads closer to the rotors in anticipation of stopping. If someone or something enters the path of the vehicle, the driver is alerted and if the brakes are not applied, the system will stop the car on its own. Their operation is similar to vehicles with adaptive cruise control. Once the distance to the vehicle in front is set, the ABS will apply the brakes as needed to maintain the clearance to the vehicle ahead.

Automatic Traction Control

Automakers use the technology and hardware of ABSs to control tire traction and vehicle stability. As explained earlier, an ABS pumps the brakes when a braking wheel attempts to go into a locked condition.

Automatic traction control (ATC) systems apply the brakes when a drive wheel attempts to spin and lose traction **(Figure 53–22)**. Manufacturers have used various basic designs for these systems and they are referred to as ATC, traction control systems (TCS), and acceleration slip reduction (ASR) systems.

Controlling wheel slip is the goal of both ABS and ATC. ABS controls negative wheel slip by modulating the hydraulic pressure to the wheel, or wheels, which is skidding. An ATC system controls positive wheel spin by modulating hydraulic pressure at the wheel that is spinning to slow down the wheel. Many systems use other methods before applying brake pressure.

ATC is most helpful on four-wheel or all-wheel drive vehicles where loss of traction at one wheel could hamper driver control. It is also desirable on high-powered front-wheel drive vehicles for the same reason. Often if traction control is fitted to a FWD vehicle, the ABS modified system is a three-channel system because ATC is not needed at the rear wheels. On RWD and 4WD vehicles, the system is based on a four-channel ABS.

In order to use the brakes to control wheel spin, the ABS must have a pump to develop hydraulic pressure and an accumulator to store reserve pressure. During braking, the driver's foot applies pressure to the brake pedal. During acceleration, the driver's foot is nowhere near the brake pedal; so if brake pressure is to be used to stop wheel spin, the brake system must have an independent source of hydraulic pressure.

During operation, the ATC system monitors the wheel-speed sensors. If a wheel enters a loss-of-traction situation, the module applies braking force to the wheel in trouble. Loss of traction is identified by comparing the vehicle's speed to the speed of the wheel. If there is a loss of traction, the speed of the wheel will be greater than expected for the particular vehicle speed. Wheel spin is normally limited to a 10 percent slippage. Some TCSs use separated hydraulic valve units and control modules for the ABS and ATC, whereas others integrate both systems into one hydraulic control unit and a single control module. The pulse rings and wheel-speed sensors remain unchanged from the ABS to the ATC.

Some ATC systems function only at low road speeds of 5 to 25 miles per hour. These systems are designed to reduce wheel slip and maintain traction at the drive wheels when the road is wet or snow covered. If during acceleration the module detects drive wheel slip and the brakes are not applied, the control module enters into the traction control mode. The inlet and outlet solenoid valves are pulsed and allow the brake to be quickly applied and released. The pump/motor assembly is turned on and supplies pressurized fluid to the slipping wheel's brake.

Engine Controls

More advanced systems work at higher speeds and integrate some engine control functions into the control loop. Most ATC systems rely on inputs available

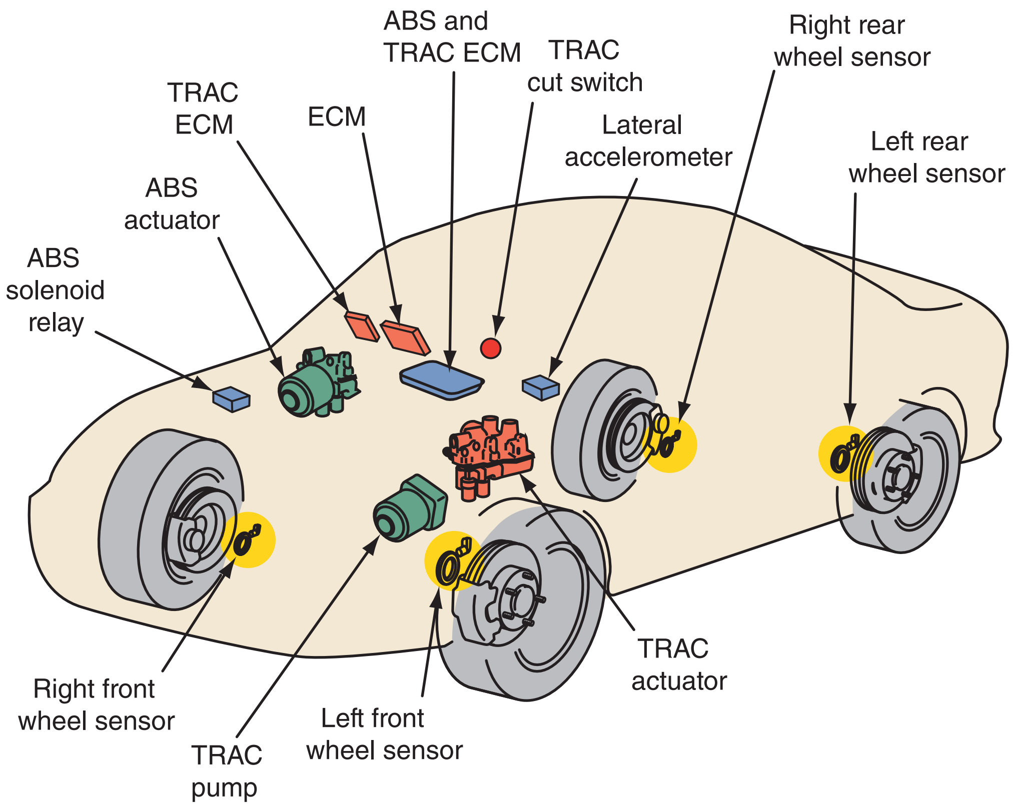

FIGURE 53–22 A typical ATC system.

on the CAN bus and compare front wheel speeds to rear wheel speeds to determine if drive wheels lose traction.

When drive wheel slip is detected while the brake is not applied, the electronic brake control module (EBCM) will enter into the traction control mode. At that time, the PCM will initiate an engine torque reduction routine to slow down the drive wheels. The following shows how the PCM reduces torque to the drive wheels:

- By retarding spark timing
- By decreasing the opening of the throttle plate
- By reducing or cutting off fuel injection pulses to one or more cylinders
- By increasing exhaust gas recirculation (EGR) flow
- By momentarily upshifting the transmission to a higher gear

If the engine torque reduction does not eliminate drive wheel slip, the EBCM will gradually apply the brakes at the driving wheels **(Figure 53–23)**. The master cylinder's isolation valve closes to isolate the cylinder from the rest of the hydraulic system. Then prime valve opens to allow the pump to accumulate brake fluid and build hydraulic pressure. The drive wheel inlet and outlet solenoid valves then open and close and pass through stages of pressure hold, pressure increase, and pressure decrease.

Driver Controls and Indicators

Most TCSs have two warning lights. However, some vehicles display the status of the system with messages on the instrument cluster. Normally, an amber lamp will illuminate or a service message will appear as any of the ABS-disabling DTCs is set. When this occurs, the TCS is automatically disabled by the control unit. When the system is actively controlling wheel spin, a green lamp lights or a message is displayed saying the system is active.

There may also be a manual cut-off switch so the driver can turn off the TCS. This will cause the amber lamp to light or a message displayed, stating the system is off.

Automatic Stability Control

Various stability control systems are found on today's vehicles. Like TCSs, stability controls are based on and linked to the ABS **(Figure 53–24)**. On some vehicles, the stability control system is also linked to the electronic suspension system. Most often, the stability control system is called an electronic stability control (ESC) system, although many other names

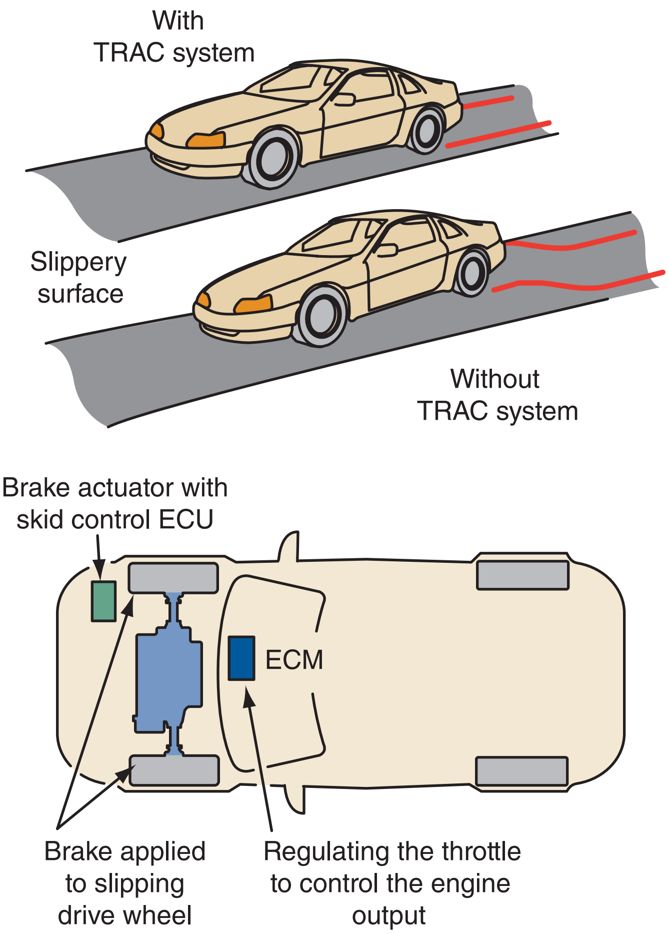

FIGURE 53–23 On this FWD vehicle, the ATC (TRAC) system applies the appropriate brakes and regulates engine output to help prevent wheel slippage when accelerating on slippery surfaces.

are used. ESC helps prevent skids, swerves, and rollover accidents. Basically the system applies the brakes at one or more wheels to help correct the steering. In some cases, power to the drive wheels is also reduced.

It is important to remember that a vehicle's tendency to roll is influenced by its height, track width, and the stiffness of its suspension. ESC cannot override a car's physical limits nor can it increase traction. If the vehicle is pushed beyond its traction limits, ESC may not be able to correct the vehicle's movement. ESC simply helps the driver maintain control using the available traction.

ESC systems can control the vehicle during acceleration, braking, and coasting. If the brakes are applied but oversteer or understeer is occurring, the fluid pressure to the appropriate brake is increased **(Figure 53–25)**. Understeer is a condition where the vehicle is slow to respond to steering changes. When the system senses understeer in a turn, the brake at the inside rear wheel is applied to regain vehicle stability. Oversteer occurs when the rear wheels try to swing around or fishtail. When this occurs, the ESC system will apply the brake at the outer rear or front wheel in an attempt to neutralize the oversteering.

The control unit, normally the EBCM, receives signals from the wheel-speed sensors, a steering angle sensor (typically part of the combination switch body behind the steering wheel), a lateral-acceleration sensor, a yaw sensor, roll sensors, and a brake-pressure sensor. It also communicates with other control units through the CAN bus **(Figure 53–26)**. The sensors basically let the control unit know the current status of the vehicle.

The ESC control unit compares the driver's intended direction (by monitoring steering angle) to

FIGURE 53–25 The effects of a stability control (ESP = Electronic Stability Program) system.

the vehicle's actual direction (by measuring lateral acceleration, yaw, and individual wheel speeds). If there is a difference between the two, the control unit intervenes by modulating individual front or rear wheels and/or reducing engine power output.

ESC continuously monitors key inputs such as yaw rate and wheel speed. **Yaw** is defined as the natural tendency of a vehicle to rotate on its vertical center axis or twist during a turn. A vehicle may also rotate naturally on its horizontal axis; this movement is called roll and pitch.

A yaw rate sensor is a gyroscopic sensor that measures the side-to-side twist of the vehicle. Two types of yaw rate sensors are used: micromechanical and piezoelectric. A micromechanical sensor relies on an oscillating element. The movement of this element is changed in response to yaw and speed. During a turn, the vehicle tends to yaw and the output from the sensor changes. The control unit uses those signals to determine how much yaw is occurring.

A piezoelectric sensor has a vibration-type gyroscope shaped like a tuning fork **(Figure 53–27)**. The device is divided into two sections: upper and lower. Both sections have piezoelectric elements attached to them. As current flows through the piezoelectric materials, the sections oscillate from one side to the other. When the vehicle is making a turn, the movement of the vehicle causes the upper elements to move away from the lower elements. This action generates an AC voltage signal that represents the vehicle's speed and yaw rate. In a right turn, the signal voltage increases and decreases when the vehicle is turning right. The output signals range from 0.25 to 4.75 volts. When the vehicle has 0 yaw, the output signal will be 2.5 volts.

The control unit looks at the actual yaw rate and compares it to the calculated desired rate. It responds to the difference between the two. This difference represents the amount of understeer or oversteer that is occurring. To correct the yaw, the system applies the brake at the appropriate wheel.

Typically the yaw rate sensor and lateral accelerometer share the same housing. They are mounted in the center of the vehicle. The lateral accelerometer monitors acceleration, deceleration, and cornering forces. These sensors are commonly Hall-effect or piezoelectric units. Semiconductor materials are placed on a plate and are set 45 degrees away from the centerline of the vehicle. The plate is supported by four beams **(Figure 53–28)**. The beams are designed to be able to flex in response to the movement of the vehicle. The amount of flex determines the output signal from the sensor. The signal can range from 0.25 to 4.75 volts depending on the G-forces the vehicle is experiencing.

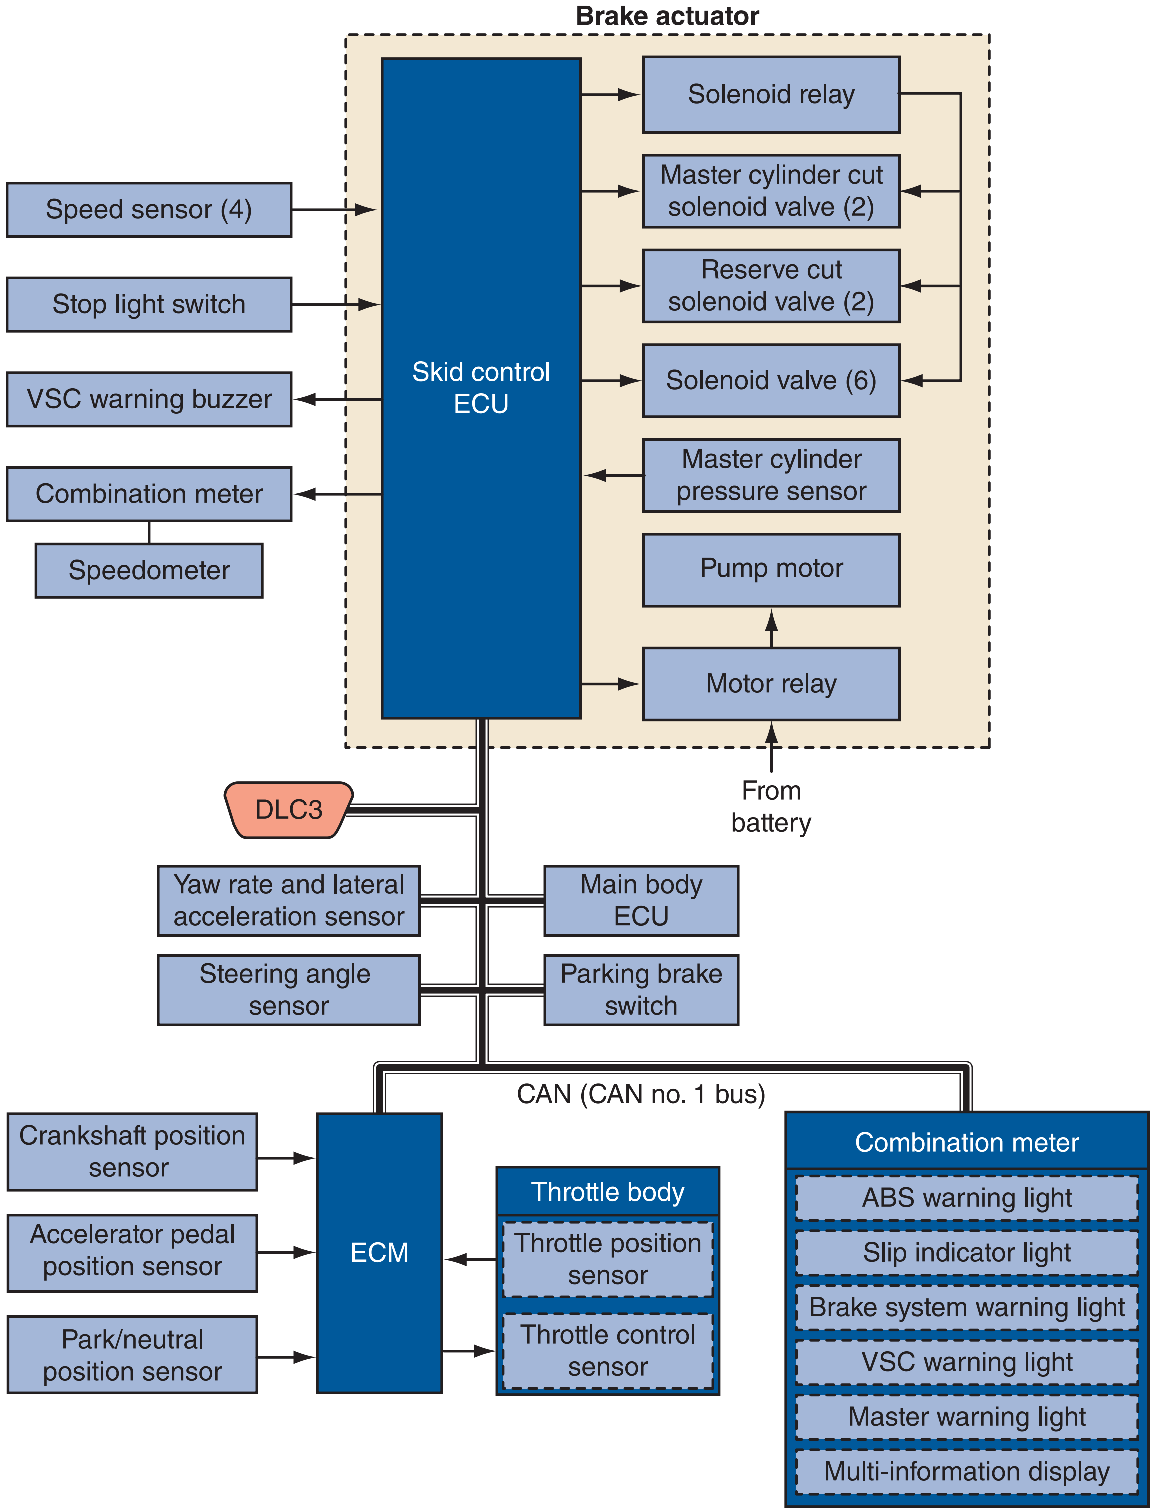

FIGURE 53–26 A typical system diagram for an ESC system.

G-force is a measurement of a vehicle's acceleration. The term is based on the normal acceleration rate due to gravity (32.174 ft./s^2 or 9.80665 m/s^2). A G-force value of 1 means the acceleration rate of the vehicle is the same as the acceleration rate of gravity. A value of less than 1 means the rate is lower than that of gravity. Values greater than 1 indicate that the forces acting on the vehicle are greater than the normal acceleration rate of gravity. Most lateral accelerometer sensors have an operating range of

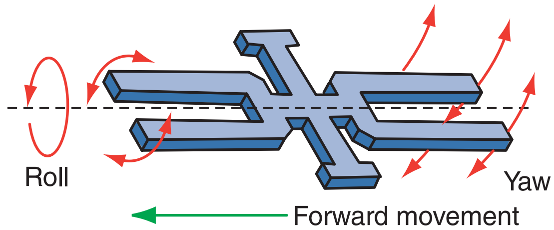

FIGURE 53–27 The basis of a yaw rate sensor.

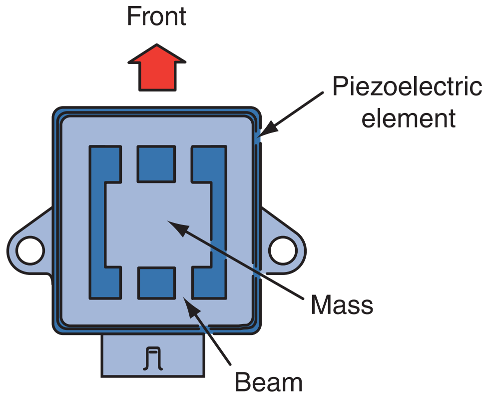

FIGURE 53–28 An acceleration/deceleration sensor. The semiconductor material rests on a plate that is supported by four beams that flex as thrust is applied in any direction.

–1.5 to +1.5 g. Zero lateral acceleration provides a 2.5-volt output signal. The voltage of the signal increases with an increase in lateral acceleration.

Stability Control System Indicators

ESC systems use an indicator light or the message center on the dash to tell the driver when the system is active (i.e., it has detected and corrected yaw rates). A lamp or the message center will also inform the driver when the system is turned off. If the control unit detects a problem in the system, it may shut down the system and alert the driver of needed service. Also, many ESC systems have an "off" switch so the driver can disable ESC, for example, when stuck in mud or snow **(Figure 53–29)**. However, ESC defaults to "on" when the ignition is restarted. When the system has been turned off by the driver, a warning lamp or message is displayed.

FIGURE 53–29 Many ESC (stability) systems have an "off" switch so the driver can disable the system.

Antilock Brake System Service

Most of the service done to the brakes of an antilock brake system are identical to those in a conventional brake system. There are, however, some important differences. Always refer to the recommended procedures in the appropriate service information before attempting to service the brakes on an ABS-equipped vehicle.

Many ABS components are simply remove-and-replace items. Normal brake repairs, such as replacing brake pads, caliper replacement, rotor machining or replacement, brake hose replacement, master cylinder or power booster replacement, or parking brake repair, can all be performed as usual. In other words, brake service on an ABS-equipped vehicle is similar to brake service on a conventional system with a few exceptions. Before beginning any service, check the service information. It may be necessary to depressurize the accumulator to prevent personal injury from high-pressure fluid.

Safety Precautions

- When replacing brake lines and/or hoses, always use lines and hoses designed for and specifically labeled for use on ABS vehicles.
- Never use silicone brake fluids in ABS vehicles. Use only the brake fluid type recommended by the manufacturer (normally DOT 3 or 4).
- Never begin to bleed the hydraulic brake system on a vehicle equipped with ABS until you have checked the service information for the proper procedure.
- Never open a bleeder screw or loosen a hydraulic brake line or hose while the ABS is pressurized.
- Disconnect all vehicle computers, including the ABS control unit, before doing any electrical welding on the vehicle.

- Never disconnect or reconnect electrical connectors while the ignition switch is on.
- Never install a telephone or CB antenna close to the ABS control unit or any other control module or computer.
- Check the wheel-speed sensor to sensor ring air gap after any parts of the wheel-speed circuit have been replaced.
- Keep the wheel sensor clean. Never cover the sensor with grease unless the manufacturer specifies doing so; in those cases, use only the recommended type.
- When replacing speed (toothed) rings, never beat them on with a hammer. These rings should be pressed onto their flange. Hammering may result in a loss of polarization or magnetization.

Relieving Accumulator Pressure

Some services require that brake tubing or hoses be disconnected. Many ABSs use hydraulic pressures as high as 2,800 psi (19,300 kPa) and an accumulator to store this pressurized fluid. Before disconnecting any lines or fittings in many systems, the accumulator must be fully depressurized. A common method of depressurizing the ABS follows:

1. Turn the ignition switch to the off position.
2. Pump the brake pedal between twenty-five and fifty times.
3. The pedal should be noticeably harder when the accumulator is discharged.

Procedures for depressurizing the system vary with the design of the system. Always refer to the service information.

Diagnosis and Testing

Always follow the vehicle manufacturer's procedures when diagnosing an ABS. In general, ABS diagnostics requires three to five different types of testing that must be performed in the specified order listed in the service information. Types of testing may include the following:

1. Prediagnostic inspections and test drive
2. Warning light symptom troubleshooting
3. On-board ABS control module testing (trouble code reading)
4. Individual trouble code or component troubleshooting

Caution! Following the wrong sequence or bypassing steps may lead to unnecessary replacement of parts or incorrect resolution of the symptom. The information and procedures given in this chapter are typical of the various antilock systems on the market. For specific instructions, consult the vehicle's service information.

Prediagnostic Inspection

Before undertaking any actual checks, take a few minutes to talk with the customer about his or her ABS complaint. The customer is a very good source of information, especially when diagnosing intermittent problems. Make sure you find out what symptoms are present and under what conditions they occur.

All ABSs have some sort of self-test. This test is activated each time the ignition switch is turned on. You should begin all diagnosis with this simple test.

Warning Lamps Place the ignition switch in the start position while observing both the red brake system light and amber ABS indicator lights **(Figure 53–30)**. Both lights should turn on. Start the vehicle. The red brake system light should quickly turn off. This lamp will stay illuminated if the brake fluid level is low, the parking brake switch is closed, or the bulb test switch section of the ignition switch is closed, or when certain ABS trouble codes are set.

With the ignition switch in the run position, the antilock brake control module will perform a preliminary self-check on the antilock electrical system. The self-check takes 3 to 6 seconds, during which

FIGURE 53–30 The warning lights for a typical ABS-, ATC-, and ESC-equipped vehicle.

time the amber antilock indicator light remains on. Once the self-check is complete, the ABS indicator light should turn off. If any malfunction is detected during this test, the amber lamp will either flash or light continuously to alert the driver of the problem. In some systems, a flashing ABS indicator lamp indicates that the control unit detected a problem but has not suspended ABS operation. However, a flashing ABS indicator lamp is a signal that repairs must be made to the system as soon as possible.

A solid ABS indicator lamp indicates that a problem has been detected that affects the operation of ABS. No antilock braking will be available, but normal, nonantilock brake performance will remain. In order to regain ABS braking ability, the ABS system must be serviced.

If both brake indicators stay on and the parking brake is fully released, the front-to-rear braking distribution system may be shut down due to a pressure loss.

If the lamp does not light when the ignition is turned on, the computer probably will not go into its self-test mode. The problem may be as simple as a burned-out bulb, or it may be a problem with the computer itself. To identify the cause for the bulb not illuminating, begin by checking the bulb. If the bulb is good, you will need to make some voltage tests at a diagnostic connector. Follow the testing procedures given by the manufacturer. Nearly all diagnostic connectors have a ground terminal that is used for one or more test modes. Use a voltmeter or ohmmeter to check the continuity between the diagnostic ground terminal and the battery negative terminal. High ground resistance or an open circuit can keep the computer out of the self-test mode and may be a clue to other system problems.

Various other terminals on the diagnostic connector may have other levels of voltage applied to them at different times. Some may have battery (system) voltage under certain conditions, whereas others may have 5 volts, 7 volts, or a variable voltage applied to them.

SHOP TALK Dirty or damaged wheel-speed sensors and damaged sensor wiring harnesses are leading triggers to turn on ABS warning lamps. Do not rush to condemn the ABS computer or hydraulic module before checking the speed sensors and tone wheels.

Visual Inspection

The prediagnosis inspection consists of a quick visual check of system components. Problems can often be spotted during this inspection, which can eliminate the need to conduct other more time-consuming procedures. This inspection should include the following:

1. Check the master cylinder fluid level.
2. Inspect all brake hoses, lines, and fittings for signs of damage, deterioration, and leakage. Inspect the hydraulic modulator unit for any leaks or wiring damage.
3. Inspect the brake components at all four wheels. Make sure that no brake drag exists and that all brakes react normally when they are applied.
4. Inspect for worn or damaged wheel bearings that may allow a wheel to wobble.
5. Check the alignment and operation of the outer CV joints.
6. Make sure the tires meet the legal tread depth requirements and that they are the correct size.
7. Inspect all electrical connections for signs of corrosion, damage, fraying, and disconnection.
8. Inspect the wheel-speed sensors and their wiring. Check the air gaps between the sensor and ring, and make sure these gaps are within the specified range. Also check the mounting of the sensors and the condition of the toothed ring and wiring to the sensor.

Test Drive

After the visual inspection is completed, test drive the vehicle to evaluate the performance of the entire brake system. Begin the test drive with a feel of the

SHOP TALK Many vehicles have the WSS built into the wheel bearing assembly and a worn wheel bearing can affect ABS operation.

SHOP TALK Remember that faulty base brake system components may cause the ABS to shut down. Do not condemn the ABS too quickly.

brake pedal while the vehicle is sitting still. Then accelerate to a speed of about 20 mph (32 km/h). Bring the vehicle to a stop using normal braking procedures. Look for any signs of swerving or improper operation. Next, accelerate the vehicle to about 25 mph (40 km/h) and apply the brakes with firm and constant pressure. You should feel the pedal pulsate if the antilock brake system is working properly.

Perform several low-speed parking maneuvers while turning the wheels. This places the front wheel bearings under load. Many front wheel speed sensors are built into the front wheel bearings and hubs and worn bearings can cause unwanted ABS activation at low speeds. If the ABS activates when parking, check for loose and worn wheel bearings.

During the test drive, both brake warning lights should remain off. If either of the lights turns on, take note of the condition that may have caused it. After you have stopped the vehicle, place the gear selector into park or neutral and observe the warning lights. They should both be off.

If the control module detects a problem with the system, the amber ABS indicator lamp will either flash or light continuously to alert the driver of the problem. In some systems, a flashing ABS indicator lamp indicates that the control unit detected a problem but has not suspended ABS operation. However, a flashing ABS indicator lamp is a signal that repairs must be made to the system as soon as possible.

A solid ABS indicator lamp indicates that a problem has been detected that affects the operation of ABS. No antilock braking will be available, but normal, nonantilock, brake performance will remain. In order to regain ABS braking ability, the ABS must be serviced.

The red brake warning lamp will be illuminated when the brake fluid level is low, the parking brake switch is closed, the bulb test switch section of the ignition switch is closed, or when certain ABS trouble codes are set.

Intermittent problems can often be identified during the test drive. If the scan tool is equipped with a “snap-shot” feature, use it to capture system performance during normal acceleration, stopping, and turning maneuvers. If this does not reproduce the malfunction, perform an antilock stop on a low coefficient surface such as gravel, from approximately 30 to 50 mph (48 to 80 km/h) while triggering the snapshot mode on the scan tool.

Self-Diagnostics

The control module monitors the electromechanical components of the system. A malfunction of the system will cause the control module to shut off or inhibit the system. However, normal power-assisted braking remains. Malfunctions are indicated by a warning indicator in the instrument cluster. The system is self-monitoring. When the ignition switch is placed in the run position, the ABS control module will perform a preliminary self-check on its electrical system indicated by a second illumination of the amber ABS indicator in the instrument cluster. During vehicle operation, the control module monitors all electrical ABS functions and some hydraulic functions during normal and antilock braking. With most malfunctions of the ABS, the amber ABS indicator will be illuminated and a DTC recorded.

The electronic control system of most ABSs includes sophisticated on-board diagnostics that, when accessed with the proper scan tool, can identify the source of a problem within the system. Each of the DTCs represents a specific possible problem in the system **(Figure 53–31)**. The service information contains a detailed step-by-step troubleshooting chart for each DTC.

Each system has its own self-diagnostic capabilities. Data available for troubleshooting includes wheel-speed sensor readings, vehicle speed, battery voltage, individual motor and solenoid command status, warning light status, and brake switch status. Numerous trouble codes are programmed into the control module to help pinpoint problems. Other diagnostic modes store past trouble codes. This data can help technicians determine if an earlier fault code, such as an intermittent wheel-speed sensor, is linked to the present problem, such as a completely failed wheel sensor. Another mode enables testing of individual system components.

Testers and Scanning Tools

Different vehicle manufacturers provide ABS test and scan tools with varying capabilities **(Figure 53–32)**. Some testers are used simply to access the digital trouble codes. Others may also provide functional test modes for checking wheel sensor circuits, pump operation, solenoid testing, and so forth. Current ABSs are tied to the CAN bus and do not require special testers.

On some vehicles, the amber ABS light and red brake light flash out the digital trouble codes. As you can see, it is important to research the capabilities and proper use of the test equipment the vehicle manufacturer provides. Misuse of test equipment can be dangerous. For example, connecting test equipment during a test drive that is not designed for this use may lead to loss of braking ability.

FIGURE 53-32 A hand-held antilock brake system scan tool.

Once all system malfunctions have been corrected, clear the ABS' DTCs. Codes cannot be erased until all codes have been retrieved, all faults have been corrected, and the vehicle has been driven above a set speed (usually 18 to 25 mph [30 to 40 km/h]). It may be necessary to disconnect a fuse for several seconds to clear the codes on some systems. After service work is performed on the ABS, repeat the previous test procedure to confirm that all codes have been erased.

Testing Components with ABS Scan Tools

ABS scan tools and testers can often be used to monitor and/or trigger input and output signals in the ABS. This allows you to confirm the presence of a suspected problem with an input sensor, switch, or output solenoid in the system. You can also check that the repair has been successful before driving the vehicle. Manual control of components and automated functional tests are also available when using many diagnostic testers. Details of typical functional tests follow.

> **Warning!** Certain components of the ABS are not intended to be serviced individually. Do not attempt to remove or disconnect these components. Only those components with approved removal and installation procedures in the manufacturer's service information should be serviced.

Testing Components with a Lab Scope

Like most electrical/electronic systems, antilock brake traction control and stability control system components can be tested with a lab scope. A lab scope offers one distinct advantage over many other testing tools. You can watch the component's activity over time. For example, all antilock-based systems rely on the cycling of solenoid valves. When looking at the solenoid on the lab scope, you should see a change in the waveform as soon as ABS operation begins. When a wheel tries to slip, the ABS control module should begin pulsing the solenoid to that wheel.

A critical input to the antilock brake, traction control, and stability control systems is from the wheel sensors. These too can be monitored on a lab scope **(Figure 53–33)**. As the wheel begins to spin, the waveform of a PM sensor's output should begin to oscillate above and below zero volts. The oscillations should get taller as speed increases. If the wheel's speed is kept constant, the waveform should also stay constant. Photo Sequence 50 shows the normal way to check a wheel-speed sensor with a lab scope.

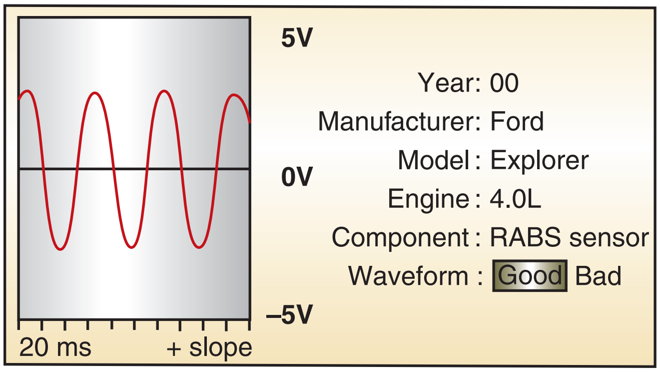

FIGURE 53-33 The waveform from a wheel-speed sensor.

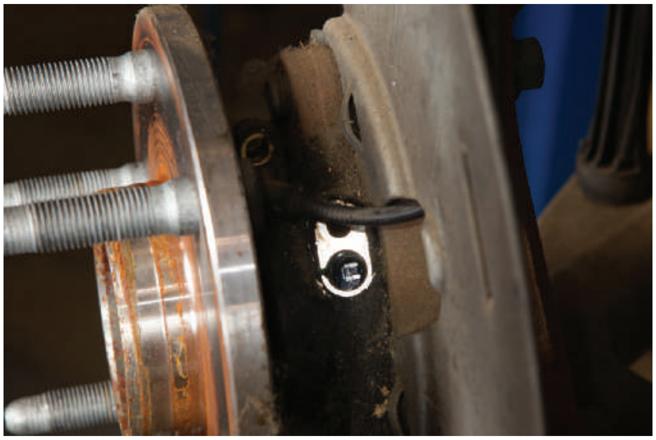
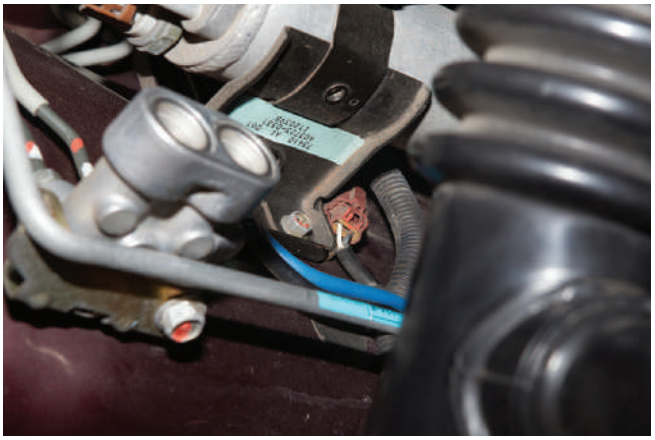
PHOTO SEQUENCE 50

Inspect/Test a Wheel-Speed Sensor with Scope

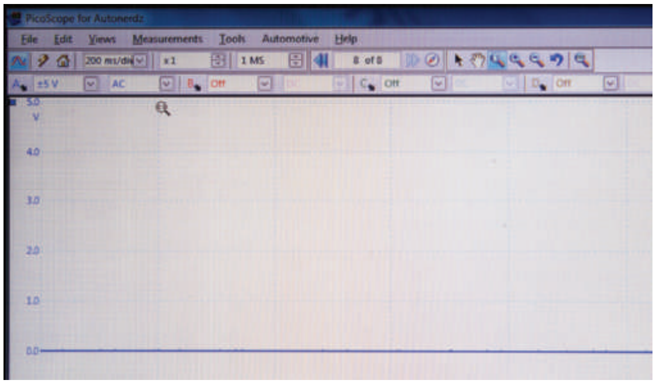


P50-1 Begin by inspecting the tone ring of the wheel-speed sensor for chipped teeth or cracks in the ring. Damage to the ring will affect sensor output.

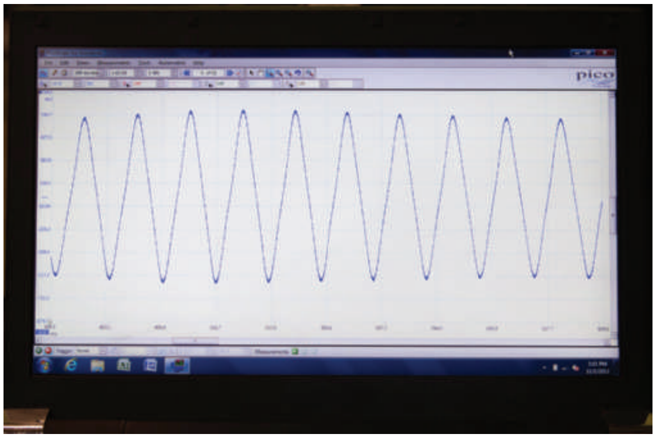


P50-2 Locate the wheel-speed sensor connection to the harness.

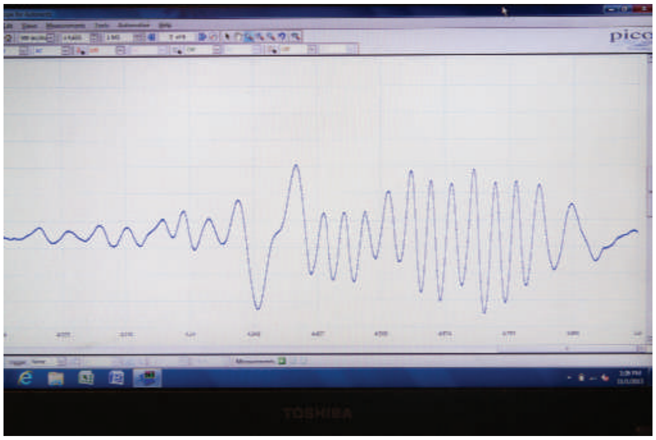
P50-3 Using two back probe pins, back probe the connector so that the scope can be connected to the sensor circuit.



P50-4 Set the scope to display AC voltage over a period of several seconds. Because the output is low, set the voltage to read less than 5 volts if possible.



P50-5 Rotate the wheel by hand and observe or freeze the scope pattern. The pattern should show a uniform positive and negative voltage as the wheel spins.



P50-6 This sensor pattern shows how a damaged tone ring affects the output of the sensor signal. The crack in the tone ring causes a variation in the signal due to the disruption of the magnetic fields between the sensor and the tone ring.

Component Replacement

A typical antilock braking system consists of a conventional hydraulic brake system (the base system) plus a number of antilock components. The base brake system consists of a vacuum power booster, master cylinder, front disc brakes, rear drum or disc brakes, interconnecting hydraulic tubing and hoses, a low fluid sensor, and a red brake system warning light.

Antilock components are added to this base system to provide antilocking braking ability. Most ABSs use the same operational principles, but the major components may be configured and/or named differently.

The electrical components of the ABS are generally very stable. Common electrical system failures are usually caused by poor or broken connections. Other common faults can be caused by malfunction of the wheel-speed sensors, pump and motor assembly, or the hydraulic module assembly.

Many of the components of ABSs are serviced by replacement only. On some systems, wheel-speed sensors must be adjusted. Normal brake repairs, such as replacing brake pads, caliper replacement, rotor machining or replacement, brake hose replacement, master cylinder or power booster replacement, or parking brake repair, can all be performed as usual. In other words, brake service on an ABS-equipped vehicle is similar to service on a conventional system with a few exceptions.

Always refer to the service information for the correct adjustment and replacements procedures for any and all brake parts in an ABS.

Wheel-Speed Sensor Service

Visually inspect each wheel-speed sensor pulsers for chipped or damaged teeth. Use a feeler gauge to measure the air gap between the sensor and rotor **(Figure 53–34)**. Check the gap while rotating the drive shaft, wheel, or rear hub unit by hand. If there is a specification on this gap, make certain the gap is within the required specification (typically 0.02 to 0.04 inch or 0.4 to 1.0 mm). If the gap exceeds specifications, the problem is likely a distorted knuckle that should be replaced.

Also check for a buildup of metal and rust on the sensor. Some sensors have a very strong magnet that will attract metal from all around the area. This buildup can cause the sensor to have inaccurate readings. If the collected material cannot be cleaned, replace the sensor.

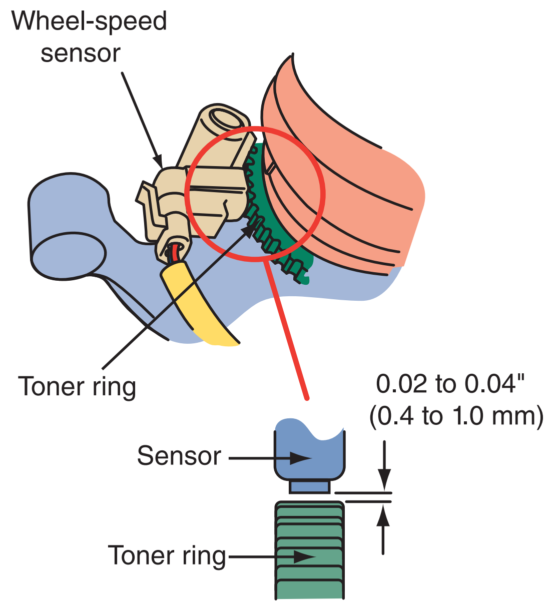


FIGURE 53-34 Wheel-speed sensor gap measurement.

Sensors are replaced by simply disconnecting the wiring at the sensor and unbolting the fasteners. Be careful not to twist the wiring cables or harness when installing the sensors. Many vehicles have a jumper harness made of highly flexible twisted pair wiring between each wheel-speed sensor and the main wiring harness. Many wheel-speed sensors are PM generators that have AC voltage outputs. Radio signals are also AC-modulated signals; therefore, the signal produced by PM generators can be affected by radio frequency interference (RFI). The wires to and from a PM generator must be shielded from other wires in the vehicle that radiate electromagnetic interference (EMI). Because the suspension must be able to move as the vehicle travels, the electrical wiring to the wheel-speed sensors cannot be shielded in conduit. Instead the wires are twisted at least one turn for every 1.75 inches. These are not serviceable and must be replaced if they are damaged or corroded. Never attempt to solder, splice, or crimp these harnesses because eventual failure will likely result.

Brake System Bleeding This is one service area that is most likely to vary with the different designs of the ABS. Always refer to the service information before attempting to bleed the brake system on a vehicle with ABS.

Some systems require that the accumulator be depressurized and the power source to the ABS control module be disconnected. Depressurizing the accumulator often requires pumping the brake pedal up to 40 times. After these have been done, the

system can be bled like a conventional brake system. On other systems, the bleeder screws are opened while the system is turned on, and they have one procedure for the front brakes and another for the rear brakes.

Failure to follow the correct procedure can result in personal injury, destruction of ABS components, or the trapping of more air in the system.

Testing Traction and Stability Control Systems

When troubleshooting a traction or stability control system, it is important to remember that the systems will be automatically disabled by the control unit if a fault occurs. Because TCS and ESC are combined with ABS and share many input signals and output functions, TCS and ESC will be disabled if an ABS fault occurs.

Traction and stability control systems add very few, if any, extra components to a vehicle. The operation of these systems is principally based on altering the control programs of the brake and engine control systems. It follows then that TCS and ESC testing should be based on retrieving DTCs and then testing individual components. Scan tools can read trouble codes and operating system data. The scan tool will also identify any communications errors that may be present. Proper communications is important for both traction and stability control systems. As with other electronic tests, you should refer to the manufacturer's troubleshooting procedures for the vehicle you are servicing.

New Trends

The widespread use of ABS has allowed engineers to pursue many different features for an automobile. Not only have ABS, traction control, and stability control systems advanced, but the entire brake system is in a state of evolution.

Brake-by-Wire

In a brake-by-wire system, the braking command of the brake pedal is electronically processed. A control module receives sensor input from the brake pedal and activates the master cylinder **(Figure 53–35)**. For safety purposes, the normal linkage from the pedal to the master cylinder may still exist. The

FIGURE 53–35 The layout for a brake-by-wire system.

advantage of brake-by-wire is simply that the pressure on the pedal can be immediately and directly relayed to the master cylinder and wheel brakes. Brake-by-wire is currently used in electric vehicles and HEVs so that braking energy can be captured and used to recharge the battery.

In a true brake-by-wire system, the hydraulic system has been totally eliminated; these systems are currently being analyzed.

Electronic Wedge Brake (EWB)

Much development is being done with electronic wedge brakes **(Figure 53–36)**. This system is totally electrically operated and electronically controlled. There is no hydraulic system. This development opens the door for brake-by-wire systems. One of

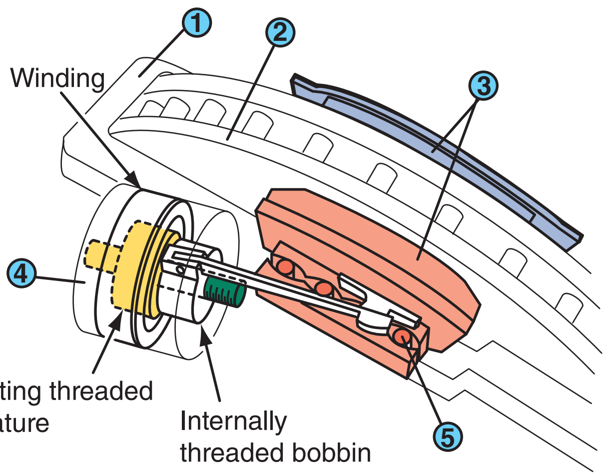

FIGURE 53–36 The layout of an electronic wedge brake. The brake caliper (1) spans the brake disc (2) on two sides. The brake disc is braked by a pad (3) that is moved by an electric motor (4) via several rollers (5) along wedge-shaped faces.

the obstacles to brake-by-wire systems has been providing enough clamping power on the rotor to safely stop the vehicle. The electronic wedge brake uses metal wedges with a series of interlocking triangular teeth between the caliper and the disc.

The wedges are designed to react to the speed of the wheels; as speed increases, so does the clamping pressure of the brakes. When the pad is pushed against the rotor, the momentum of the rotating disc draws the pads farther up the interlocking series of wedges, applying greater braking pressure and increasing braking efficiency. This allows for the use of a low-power 12-volt electric motor to initially push the brake pad toward the rotor. The motor turns roller screws that press the wedge and pads against the rotor.

The system relies on the vehicle's battery for power but also has a built-in backup battery. This is important because one of the fears of brake-by-wire systems is the loss of power. Because the system uses a low-power motor, a small backup battery can power the brakes if needed. Also, as a safety feature, each wheel brake in the system is independent of the others. This means if one brake fails, there are three others that can be used to stop the vehicle. The system can also quickly retract the pads when the brake pedal is released; this reduces brake drag and allows for ABS cycling to occur up to six times faster.

It is claimed that EWB systems greatly shorten stopping distances, require much less energy than hydraulic brakes, allow for much better control in ATC and ESC systems, are light, and are more reliable and durable than hydraulic brake systems.

Several suppliers, such as Siemens VDO, Continental AG, Robert Bosch LLC, Delphi Corporation, and TRW Automotive, also are working on electromechanical brake programs.

SUMMARY

- Brake fluid is the lifeblood of any hydraulic brake system. DOT 3 is recommended for most antilock brake systems and some power brake systems.
- Modern antilock brake systems provide electronic/hydraulic pumping of the brakes for straight-line stopping under panic conditions.
- In addition to being classified as integral and nonintegral, antilock brake systems can be divided into the level of control they provide. They can be one-, two-, three-, or four-channel, two- or four-wheel systems.
- Pressure modulation works to prevent wheel locking. Antilock brake systems can modulate the pressure to the brakes as often as fifteen times per second.
- Integrated antilock brake systems combine the master cylinder, hydraulic booster, and hydraulic

circuitry into a single assembly. On a nonintegrated ABS, the master cylinder and hydraulic valve unit are separate assemblies and a vacuum boost is used. In some nonintegrated systems, the master cylinder supplies brake fluid to the hydraulic unit.

- Automatic traction control (ATC) is a system that applies the brakes when a drive wheel attempts to spin and loses traction.
- Automatic stability systems correct oversteer and understeer by applying one wheel brake.
- Malfunction of the ABS causes the electronic control module to shut off or inhibit the system. However, normal power-assisted braking remains. Malfunctions are indicated by one or two warning lights inside the vehicle.
- Loss of hydraulic fluid or power booster pressure disables the antilock brake system.

HEATING AND AIR CONDITIONING

OBJECTIVES

- Identify the common parts of a heating system.
- Describe the operation of the vacuum and mechanical controls of a heating system.
- Diagnose temperature control problems in the heater/ventilation system.
- Describe how an automotive air-conditioning system operates.
- Describe how refrigerants are used in the air-conditioning system.
- Locate, identify, and describe the function of the various air-conditioning components.
- Describe the operation of the types of air-conditioning control systems.

The first automobiles had few features that provided for driver and passenger comfort. In winter, heavy coats and blankets were all that allowed passengers to survive the bitter cold and freezing winds. In summer, the breeze generated by 15 mph (25 km/h) travel was the only thing that cooled the passengers.

Today's vehicles have ventilation, heating, and air-conditioning systems to provide passenger comfort. Ventilation and heating systems are standard equipment on all passenger vehicles and air conditioning is standard on most and available for nearly all. These systems move heat to warm or cool the passengers.

Ventilation System

The ventilation system on most vehicles is designed to supply outside air to the passenger compartment through upper or lower vents or both. Several systems are used to vent air into the passenger compartment, the most common of which is the flow-through system **(Figure 54–1)**. In this arrangement, a supply of outside air, called ram air, flows into the car when it is moving. When the car is not moving, a steady flow of outside air can be produced by the heater fan. In operation, ram air is forced through an inlet grille. The pressurized air then circulates throughout the passenger and trunk compartment. From there the air is forced outside the vehicle through an exhaust area.

Rather than using ram air (especially if the vehicle is stopped), a ventilation fan can be used. It can be accessible from under the dashboard or from inside the engine compartment. A blower motor and fan assembly is placed inside the blower housing. As the fan, often called a squirrel cage, rotates, it produces a strong suction on the intake. A pressure is also created on the output. When the fan motor is energized by using the temperature controls on the dashboard, air is moved through the passenger compartment. Most vehicles have a cabin filtration system that cleans the air before it enters the passenger compartment.

Automotive Heating Systems

The heating system's primary job is to provide a comfortable passenger compartment temperature and to keep car windows clear of fog or frost. The heating system works together with the engine's cooling system to maintain proper temperatures inside the car.

GO TO Chapter 14 for details of the engine cooling system.

To meet federal safety standards, all vehicles must be equipped with passenger compartment heating and windshield defrosting systems. The main components of an automotive heating system are the heater core, the heater control valve, the blower motor and the fan, and the heater and defroster ducts **(Figure 54–2)**. The heating system works with the engine's cooling system and converts the heat from the coolant circulating inside the engine to hot air, which is blown into the passenger compartment.

SHOP TALK

In most vehicles, the air conditioning will turn on when the defroster is selected by the driver and the ambient temperature is more than 35 °F (1.67 °C). This is done to remove moisture from the vehicle's interior.

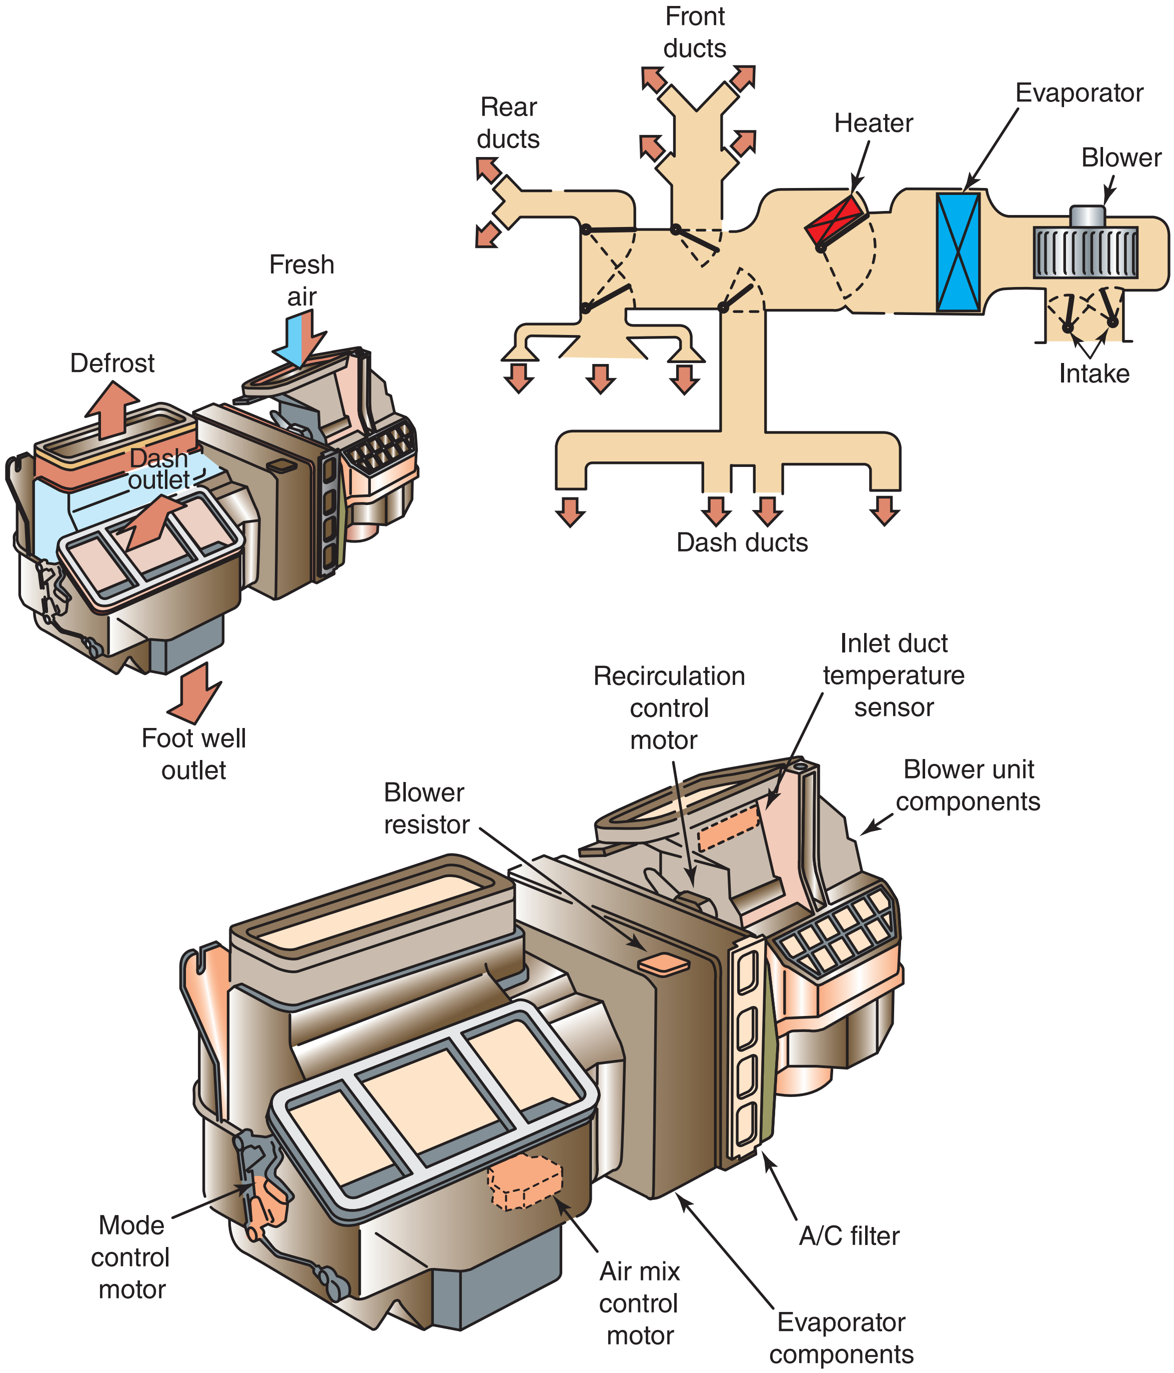

FIGURE 54–2 A typical HVAC airflow and components for the heater and air conditioning system.

In the liquid-cooling system, heat from the coolant circulating inside the engine is converted to hot air, which is blown into the passenger compartment. Hot coolant from the engine is transferred by a heater hose to the heater control valve and then to the heater core inlet **(Figure 54–3)**. As the coolant circulates through the core, heat is transferred from the coolant to the tubes and fins of the core. Air blown through the core by the blower motor and fan then picks up the heat from the surfaces of the core and transfers it to the passenger compartment of the car. After giving up its heat, the coolant is then pumped out through the heater core outlet, where it is returned to the engine to be heated again.

Heater Core

The **heater core** is generally designed and constructed much like a miniature radiator **(Figure 54–4)**.

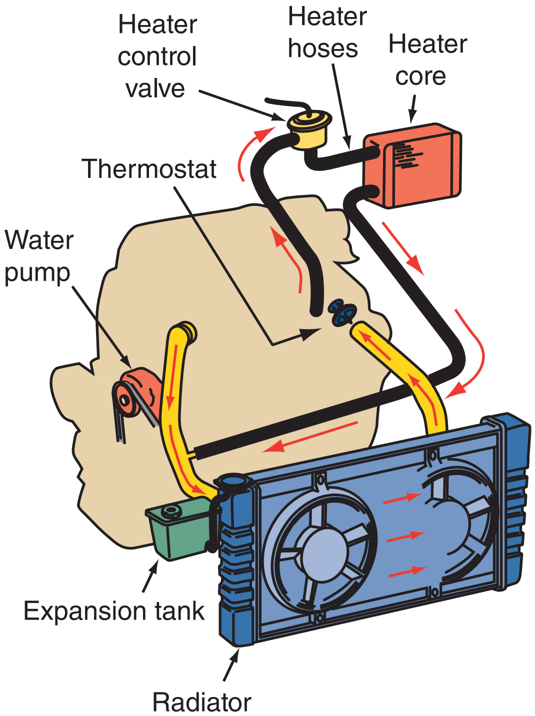

FIGURE 54-3 Hot coolant from the engine is sent from the upper portion of the engine to the heater core.

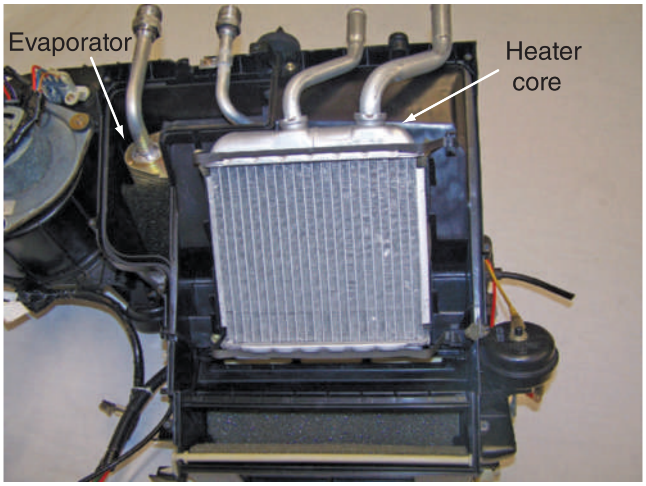

FIGURE 54-4 A heater core.

It features an inlet or outlet tube and a tube and fin core to facilitate coolant flow between them.

Although all heater cores basically function in the same manner, several variations in design and materials are used by different automakers to achieve the same results. Although the core construction varies, this type has an aluminum core with plastic tanks.

Heater Control Valve

The **heater control valve** (sometimes called the water flow valve) controls the flow of coolant into the heater core from the engine. In a closed position, the valve allows no flow of hot coolant to the heater core, keeping it cool. In an open position, the valve allows heated coolant to circulate through the heater core, maximizing heater efficiency. Heater control valves are operated in several ways: by cable, thermostat, vacuum, or electronically. Some vehicles do not use a heater control valve; rather, a heater door controls how much heat is released into the passenger compartment from the heater core.

Cable-operated valves are controlled directly from the heater control lever on the dashboard. Thermostatically controlled valves feature a liquid-filled capillary tube located in the discharge air stream off the heater core. This tube senses air temperature, and the valve modulates the flow of coolant to maintain a constant temperature, regardless of engine speed or temperature.

Many heater valves found in today's car are vacuum operated. These valves are normally located in the heater hose line or mounted directly in the engine block. When a vacuum signal reaches the valve, a diaphragm inside the valve is raised, either opening or closing the valve against an opposing spring. When the temperature selection on the dashboard is changed, vacuum to the valve is vented and the valve returns to its original position. Vacuum-actuated heater control valves are either normally open or normally closed designs.

Many newer vehicles use electrically controlled heater control valves. The valve may use a stepper motor to block the flow of coolant or use the motor to move a lever and block the flow as in non-electronic valves.

On late-model vehicles, heater control valves are typically made of plastic for corrosion resistance and light weight **(Figure 54–5)**. These valves feature few internal working parts and no external working parts. With the reduced weight of these valves, external mounting brackets are not required.

Systems without a Control Valve Some systems do not have a heater control valve; rather, heat inside the passenger compartment is controlled by changing the airflow over the heater core. In these systems, hot coolant always flows through the heater core. When heat is needed, air is allowed to flow through the heater core. The amount of heat is determined by the amount of air allowed to pass through the core.

Airflow is controlled by a blend door inside the blower housing. The blend door directs airflow either across the heater core or air-conditioning evaporator. This allows the driver to change the temperature of the air from the system. The movement of this

door can be controlled by a cable, vacuum, or electrically with a motor.

PTC Heaters Today's engines are designed to reduce the amount of waste heat they emit; therefore, the amount of heat available for the heating system may be limited. This is especially true with hybrid vehicles with the stop-start feature. Also, in conventional vehicles, interior heat is not available until the coolant warms up and transfers heat through the heater core.

Some late-model vehicles, especially hybrids, have an auxiliary positive temperature coefficient (PTC) unit **(Figure 54–6)** or a PTC heating element in the heater core. These heaters are able to provide warm air before the engine's coolant warms up. PTC heaters are electronically controlled and work independently of the cooling system.

When current passes through a PTC element, heat is produced and the air that passes through the heater core is warmed. Some vehicles have an additional PTC element installed in an air duct from the blower housing; this helps to increase the air temperature in the ducts.

PTC elements react quickly to changes in current. The elements are small ceramic stones. These are typically barium titanate polycrystalline ceramics doped with metals. Most PTC elements are self-regulating, which means there is no need for a thermostat to control its operation. As the element heats, its resistance increases. Once a predetermined temperature is reached, the internal resistance increases significantly, reducing current flow and preventing further increase in temperature.

Blower Motor

The blower motor is usually located in the heater housing assembly. It ensures that air is circulated through the system **(Figure 54–7)**. Its speed is controlled by a multiposition switch in the control panel. The switch works in connection with a resistor block that is usually located on the heater housing.

On some vehicles, when the engine is running, the blower motor is in constant operation at low speed. On automatic temperature control systems, the blower motor is activated only when the engine reaches a predetermined temperature. The blower motor circuit is protected by a fuse located in the fuse panel.

The blower motor resistor block is used to control the blower motor speed. The typical resistor block is composed of three or four wire resistors in series with the blower motor that control its voltage and current. The speed of the motor is determined by the control panel switch, which puts the resistors in series. Increasing the resistance in the system slows the blower speed.

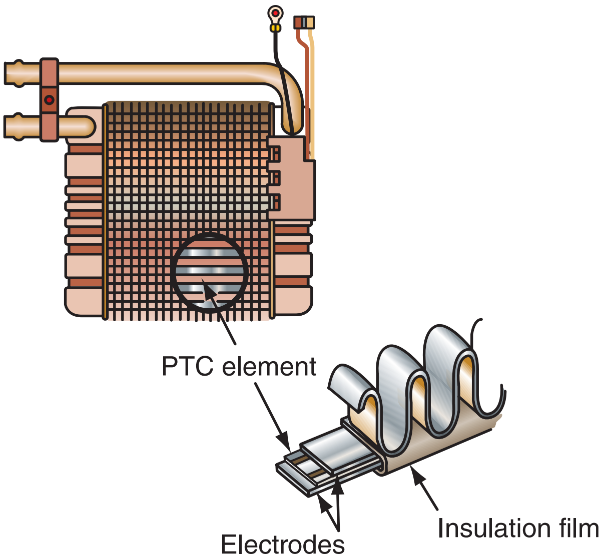

FIGURE 54–6 An electronic PTC auxiliary heater.

FIGURE 54–7 A blower motor assembly.

Vehicles with automatic climate control typically use pulse-width modulation to control blower speed. Instead of a fixed resistor block and fixed blower speeds, a control module pulses the blower motor power circuit on and off. By varying the on-time of the motor, fan speed is increased or decreased as needed.

Some late-model vehicles, including the Toyota Prius and some Mercedes-Benz models, use solar cells to power the blower motor to circulate air through the passenger compartment when the vehicle is off. The sunload and ambient temperature sensors provide input to the climate control module, which can vary blower speeds as needed. Circulating air through the cabin helps reduce the temperature and the load on the A/C system once the vehicle is restarted.

Heater and Defroster Duct Hoses

Transferring heated air from the heater core to the passenger compartment heater and defroster outlets is the job of the heater and defroster ducts. The ducts are typical parts of a large plastic shell that connects to the necessary inside and outside vents. This ductwork also has mounting points for the evaporator and heater core assemblies. Contained inside the duct are the mode doors required to direct air to the floor, dash, and/or windshield. Sometimes the duct is connected directly to the vents, whereas other times hoses are used.

Recirc/Fresh Door Many vehicles have a recirc/fresh mode. This feature allows the driver to recirculate (recirc) the air inside the vehicle. This mode is normally selected when outside air is entering the vehicle and it has unpleasant odors. Outside or fresh air normally enters the interior through the normal heating, ventilation, and A/C systems. While operating in the recirc mode, the system uses the air from the interior for those systems. A recirculation door closes off the outside airflow and opens the intake for interior air.

Some late-model vehicles use sensors to detect smog and pollution present in the incoming air. On some models, the sensor also is able to detect carbon monoxide, hydrocarbons, and oxides of nitrogen. Upon detection of contaminates, airflow is automatically switched to recirculation mode. The recirculated air passes through a dust and pollen filter and charcoal filter to remove any odors and contaminants.

Heating and A/C Systems in Hybrid Vehicles

In a hybrid electric vehicle, the engine can be used to supply the heat, so heating and defrosting systems are similar to those used in conventional vehicles. However, some hybrids have additional electrical heaters. These keep the passenger compartment warm when the engine is off.

Other systems have a 12- or 42-volt auxiliary electric water pump. This pump is used to circulate coolant through the engine to maintain heater performance during an idle stop. A heater control module operates the pump based on an idle stop signal from the PCM. If the engine's temperature drops below a predetermined level during an idle stop, the engine will restart. The system also has a temperature sensor at the heater core. This sensor monitors the activity of the electric water pump. If it senses that the heater core is losing heat quickly, the control module will assume that the pump has failed and will start the engine and set a DTC.

The cooling systems used in some hybrids feature coolant storage tanks. Hot coolant is stored in a container **(Figure 54–8)** where it can remain hot for several days. The hot coolant is circulated through the engine immediately after startup. The fluid also may circulate through the engine many hours after it is shut off. The stored coolant can provide heat for the passenger compartment and allows the engine to warm up quickly, thereby reducing emission levels during startup.

The heating and A/C system is also used on some hybrid vehicles to maintain HV battery temperature. Because temperature is important for battery efficiency, a network of heating and cooling lines may be attached to the battery box. Even if separate liquid heating and A/C lines are not used, there is a ventilation system for the HV battery. In many hybrids, such as the Prius, Honda IMA hybrids, and others, a battery ventilation fan and ductwork system is used to draw cabin air into and through the battery box. Air is then discharged outside the vehicle. It is important that the inlet for the battery cooling system not be blocked or restricted as this can increase battery temperature and set battery temperature DTCs.

Vehicles that use Li-Ion batteries, such as the Volt, have dedicated heating and A/C lines for the battery box. In addition to circulating coolant through the inverter and drive motor assemblies, the Volt uses a separate A/C evaporator, called a battery chiller, to remove heat from the battery charger and pack. Depending on operating conditions, the liquid cooling system can either be used to warm the battery pack or remove heat. When greater heat dissipation is required, the A/C compressor is turned on and the A/C system cools the battery.

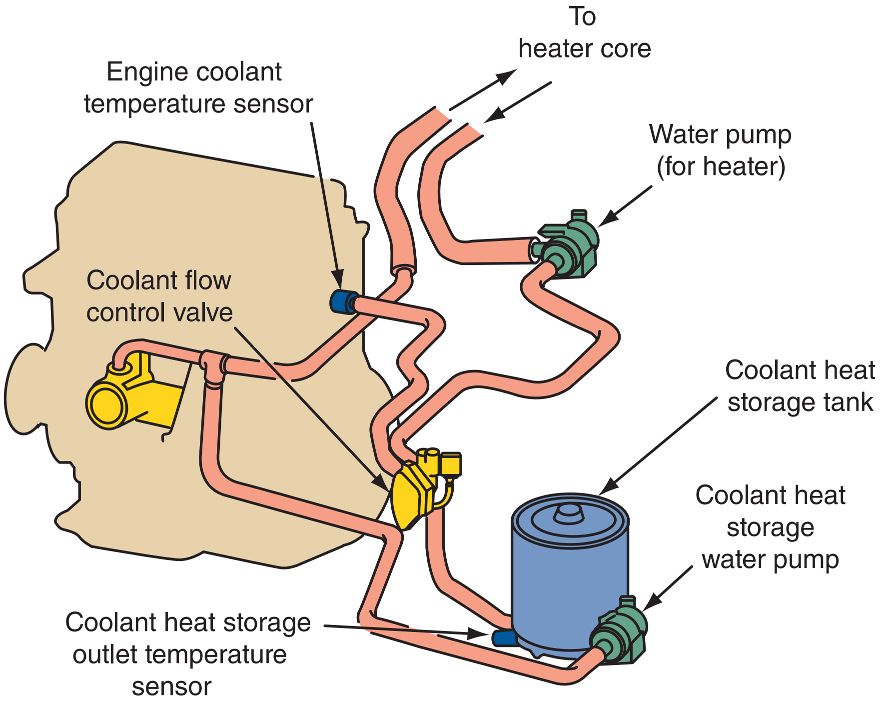

FIGURE 54-8 The coolant heat storage tank is a large vacuum-insulated container that is capable of storing hot coolant for a long period.

Heating System Service

When doing system checks and services, always follow the procedures recommended by the manufacturer. In most cases, problems with the heating system are problems with the engine's cooling system. Therefore, most service work and diagnosis are done to the cooling system. Problems that pertain specifically to the heater are few, these being the heater control valve and the heater core. Most often if these two items are faulty, the engine's cooling system will be negatively affected. Both of these items are replaced rather than repaired. Some problems will pertain only to the heater controls. In some cases, it is possible to make repairs to vacuum hose and electrical connections without removing the heater assembly. If it is necessary to remove the heater assembly, the cooling system must be drained before removing the heater core.

GO TO Chapter 14 for details on diagnosing and servicing engine cooling systems.

Basic Heater Inspection and Checks

When there is a problem of insufficient heat, begin your diagnosis with a visual inspection and a check of the coolant level and condition. If the level is correct, turn the heater controls on and run the engine until it reaches normal operating temperature. If the engine does not reach operating temperature, typically around, 220 °F (104.4 °C) suspect a faulty thermostat or fan clutch. Then measure the temperature of the upper radiator hose. The temperature can be measured with a pyrometer or thermocouple and a DMM. If these are not available, carefully touch the hose. You should not be able to hold the hose long because of the heat. While doing this, make sure you stay clear of the area around the cooling fan. A spinning fan can chop off your hand. If the temperature of the hose is not within specifications, suspect a faulty thermostat.

If the hose is the correct temperature, check the temperature of the two heater hoses. They should both be hot. If only one of the hoses is hot, suspect the problem to be the heater control valve or a plugged heater core.

Leaking heater cores are often easy to diagnose because of the presence of one or more of three symptoms: coolant leaking onto the floorboards, steam coming from the vents, and a sweet smell

inside the passenger compartment. Any of these conditions should prompt a complete inspection of the cooling system.

Heater Core Service

Like the radiator, heater core tanks, tubes, and fins can become clogged over time by rust, scale, and mineral deposits circulated by the coolant. Debris carried through the system can actually act as a sandblaster and eat away at the core from the inside, causing leaks. Feel the heater inlet and outlet hoses while the engine is idling and warm with the heater temperature control on hot. If the hose downstream of the heater valve does not feel hot, the valve is not opening.

If the heater core appears to be plugged, the inlet hose may feel hot up to the core but the outlet hose remains cool. Reverse flushing the core with a power flusher may open up the blockage, but usually the core has to be removed for cleaning or replacement. Air pockets in the heater core can also interfere with proper coolant circulation. Air pockets form when the coolant level is low or when the cooling system is not properly filled after draining.

When the heater core leaks and must be repaired or replaced, it is often a very difficult and time-consuming job, primarily because of the core's location deep within the bulkhead of the car. For this reason always leak test a replacement heater core before installation. Also flush the cooling system and replace the coolant.

The heater core is normally buried under the dash. Replacing the core may require evacuating the A/C system also. This is due to both the core and evaporator being in the same housing. Before starting to replace the core, read through the service information to determine what needs to come apart and how.

On some vehicles heater core replacement is much easier. To remove it, remove the access panel(s), drain the coolant from the system and then disconnect the heater hoses to the core. It is wise to place shop rags or towels under the core so that fluid does not leak out onto the vehicle's carpet. Unbolt the core and remove it, make sure nothing is damaged as you pull the core out. The procedure for installing a heater core follows the reverse steps as removing it.

When replacing the heater core, inspect the heater hoses and replace if necessary. Most heater hoses are molded into specific shapes and must be replaced with the same size and shape hose. Bulk heater hose can kink if bent to fit into place, reducing flow through the core. Because the heater hoses

A common procedure for servicing a cooling system is reverse flushing it. However, some manufacturers do not recommend reverse flushing their heater cores. Always check with the service information before reverse flushing a system.

can be difficult to access and remove from the core, many technicians cut the old hoses at the pipe connections and replace the hoses.

PTC Heaters PTC heaters can be checked by measuring the resistance of the heating element. If the resistance does not meet specifications **(Figure 54–9)**, the assembly should be replaced.

Heater Control Valve Service

When there is a problem with the control valve, it is typically caused by the controls or the valve itself. When the valve is bad, it should be replaced. If the heater control valve or its controls prevent the valve from opening all the way, heating will be reduced in the passenger compartment. If the valve does not completely close, the compartment will not cool properly when the A/C is turned on.

With cable-operated control valves, check the cable for sticking, slipping (loose mounting bracket), or misadjustment. With valves that are vacuum operated, there should be no vacuum to the valve when the heater is on (except for those that are normally closed and need vacuum to open).

Thermostat Service The thermostat, which helps regulate the coolant temperature in the cooling system, plays a large part in the heating system. A malfunctioning thermostat can cause the engine to overheat or not reach normal operating temperature, or it can be the cause of poor heater performance.

Late-model vehicles can set a DTC if the thermostat is not allowing the engine to reach normal operating temperature **(Figure 54–10)**. A thermostat that is stuck open or is opening too soon can often be diagnosed by watching the flow of coolant in the radiator during engine warm up or by monitoring coolant temperature. Most engines have thermostats that begin to open around 175 °F (79.4 °C) and are fully open at 195 °F (90.5 °C). If the coolant temperature remains low, not even reaching 195 °F (90.5 °C), suspect a defective thermostat.

Replacing a thermostat varies greatly from engine to engine so refer to the manufacturer's service information for details. Make sure the new thermostat is installed properly with the wax pellet oriented toward the engine. Also, make sure the thermostat seats and seals properly in its housing before tightening the housing bolts to specs. Once the thermostat has been replaced, refill the cooling system using the specified coolant and make sure all air is bled from the system.

SHOP TALK

Poor heating can be caused by many things. A low coolant level can starve the heater, resulting in little or no heat output. Check the coolant level in the radiator (not the overflow tank) to see if it is low. Air pockets can form in long heater hoses or where the heater is mounted higher than the radiator. To vent the trapped air, some vehicles have bleeder valves on the hoses. Opening the valves allows air to escape as the system is filled.

Blower Motor Service

If the blower motor does not operate, use a DMM to make sure there is voltage on both sides of the fuse. Then check to see if there is voltage and ground at the motor. Some systems supply constant power and vary the ground while others ground the motor and vary the voltage **(Figure 54–11)**. If the system uses a PWM motor, connect a scan tool and check for DTCs and try to control the blower with the scan tool. You may need to connect a meter or scope to the fan's wiring to determine if the fan control circuit is operating.

For non-PWM blower motors, if the blower motor is getting voltage and has a good ground, the problem is a burned-out blower motor. If voltage is present but the motor does not run, ground the motor to check if it operates. If the motor now works, the problem is likely an open resistor or switch. In situations where no voltage is available at the motor, backtrack to check for an open resistor, switch, or relay. Check for proper relay operation and for burned or corroded connections at the blower relays or in the bulkhead connectors. Carefully inspect all wiring and connectors in the fan circuit. A faulty connection can overheat, melting the plastic and damaging the connector and terminals.

As the blower motor ages and/or debris accumulates in the blower housing, blower motor speed can be reduced. This can cause the motor to increase its current draw. Excessive current draw by the motor can then cause burned resistors and damaged connections. Many technicians measure blower motor current draw whenever replacing a blower resistor and compare the reading to specs or against similar vehicles. If the motor is drawing more current than specified, it should be replaced.

Heater and Defroster Duct Service

If the blower motor runs but no air comes out of the ducts, the problem is either a stuck or an inoperative airflow control valve or blend door or plugged cabin filter. This can also affect the operation of the defrosters. These doors may be cable, electrically, or vacuum operated. To further diagnose the problem, change the

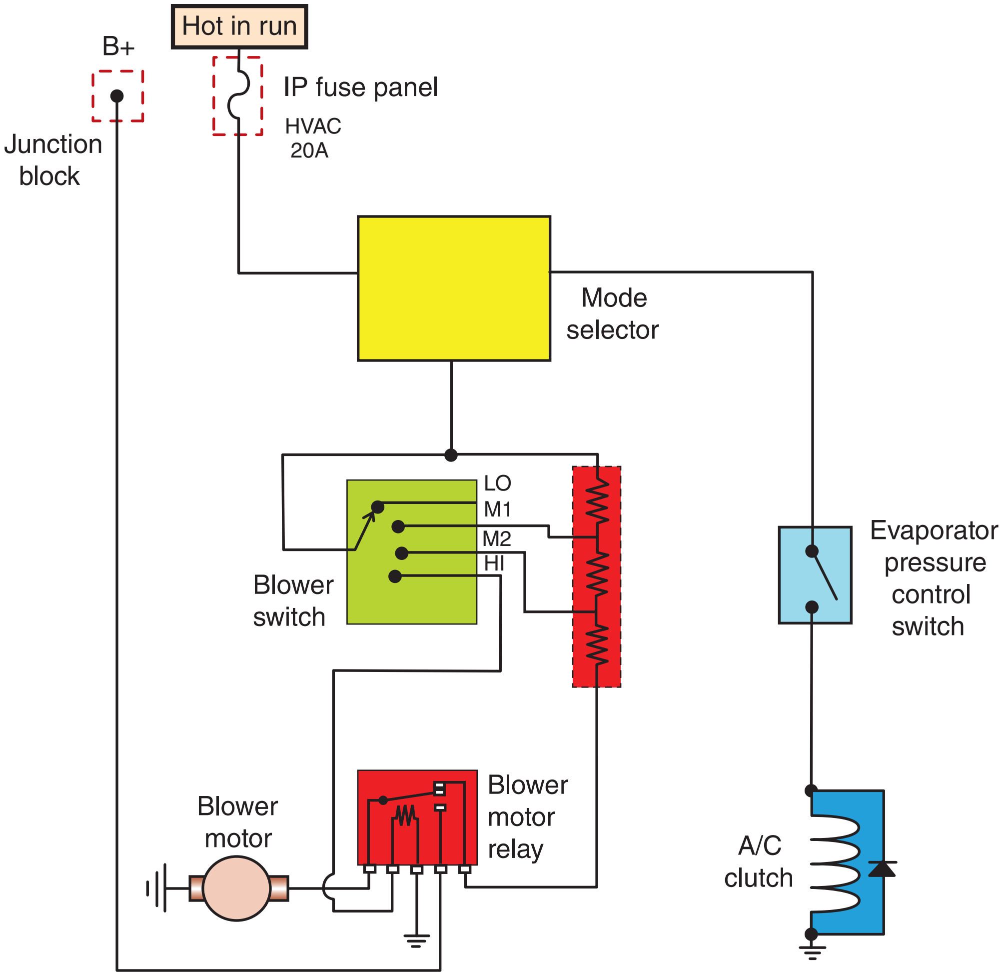

FIGURE 54-11 An example of a power-controlled blower motor circuit.

position of the temperature selector knob, sliding it from hot to cold. If you do not hear the sound of doors opening and closing, it means the control cables have slipped loose from the dash switch or door arm, which can sometimes occur, rendering the door inoperative. If this is the case, you will feel little or no resistance when sliding the temperature control knob. A kinked or rusted cable can also prevent a door from working. If this is the case, you will feel resistance when trying to move the control knob. In either case, it is necessary to get under the dash, find the cable, and then replace, reroute, or reconnect it. Doors can also be jammed by objects that have fallen down the defroster ducts. Remove the obstruction from the plenum by fishing through the heater outlet with a coat hanger or magnet, or remove the plenum. Be careful when fishing for the obstruction; some heater cores are easily pierced.

Most current HVAC systems use electric servomotors to move the various doors. Each motor is fitted with a potentiometer that sends a signal to the A/C control unit regarding the actual position of the door. If the actual position is not the same as the commanded position, most systems will set a DTC, indicating that the door is not working properly. Before proceeding with detailed diagnostics of the electrical system, make sure there are no linkage problems or that the door is not physically stuck. Normally, if the problem is electrical, the A/C control unit, servomotor, or wiring harness is faulty.

With vacuum-controlled doors, the most common causes of failure are leaky or loose vacuum hoses or defective diaphragms in the vacuum motors that move the doors. Check the vacuum by starting the engine and disconnecting the hose that goes to one of the door's vacuum motor. If you feel a vacuum or hear a hissing sound when trying different temperature settings, the vacuum source is good. Apply vacuum to the motor with a hand-held pump; if it moves and holds vacuum for about 1 minute then bleeds off, the problem is a bad vacuum motor. If it does not, check for leaky vacuum hose connections, a defective temperature control switch, or a leaky vacuum reservoir or check valve under the dash or in the engine compartment.

Theory of Automotive Air Conditioning

Air conditioning basically supplies cool air into the passenger compartment. It also removes moisture from the air. An A/C system cools the air by moving heat from the confined space of the passenger compartment to the atmosphere. The operation of all A/C systems is based on fundamental laws of nature.

GO TO Chapter 3 for a detailed discussion of these laws.

Heat Flow

An air-conditioning system is designed to pump heat from one point to another. All materials or substances, as cold as –459 °F (–273 °C), have heat in them. Below this temperature, called absolute zero, no heat energy remains. Heat always flows from a warmer object to a colder one. For example, if one object is at 30 °F (–1.1 °C) and another object is 80 °F (27 °C), heat flows from the warmer object (80 °F [27 °C]) to the colder one. The greater the temperature difference between the objects (30 °F [–1.1 °C]), the greater the amount of heat flow.

Heat Absorption

Objects can be in one of three forms: solid, liquid, or gas. When objects change from one state to another, large amounts of heat can be transferred. For example, when water temperature goes below 32 °F (0 °C), water changes from a liquid to a solid (ice). If the temperature of water is raised to 212 °F (100 °C), the liquid turns into a gas (steam). But an interesting thing occurs when water, or any matter, changes from a solid to a liquid and then from a liquid to a gas. Additional heat is necessary to change the state of the substance, even though this heat does not register on a thermometer. For example, ice at 32 °F (0 °C) requires heat to change into water, which will also be at 32 °F (0 °C). Additional heat raises the temperature of the water until it reaches the boiling point of 212 °F (100 °C). More heat is required to change water into steam. But if the temperature of the steam were measured, it would also be 212 °F (100 °C). The amount of heat necessary to change the state of a substance is called latent heat—or hidden heat—because it cannot be measured with a thermometer. This hidden heat is the basic principle behind all air-conditioning systems.

GO TO Chapter 3 for a discussion of heat and how it is measured.

Pressure and Boiling Points

Pressure also plays an important part in air conditioning. Pressure on a substance, such as a liquid, changes its boiling point. The greater the pressure on a liquid, the higher the boiling point. If pressure is placed on a vapor, the vapor condenses at a higher-than-normal temperature. In addition, as the pressure on a substance is reduced, the boiling point can also be reduced. For example, the boiling point of water is 212 °F (100 °C). The boiling point can be increased by increasing the pressure on the fluid. This is because as the pressure increases, the energy required for the water molecules to expand and turn to a gas also increases. It can also be decreased by reducing the pressure or placing the fluid in a vacuum. By reducing the pressure, the water molecules can change state at a lower temperature. If the pressure is reduced enough, water can boil at room temperature.

Relative Humidity

The amount of moisture that air can hold is directly related to the temperature of the air. The warmer the air, the more moisture it can hold. Therefore, lowering the temperature of the air extracts the moisture from the air and lowers the air's relative humidity. What we call relative humidity is the amount of moisture in the air compared to the amount the air can actually hold at that temperature. If the air cannot hold any more moisture, it condenses back into water. This is what causes dew and condensation on surfaces. For many people, low relative humidity is typically more comfortable than high humidity.

Refrigerants

An air-conditioning (A/C) system is designed to move heat from one point to another. In an automobile, heat is removed from the passenger compartment and moved to outside the vehicle. The substance used to move the heat is called the **refrigerant**.

Before 1994, most automotive A/C systems used a refrigerant called Refrigerant-12 (commonly referred to as R-12 and Freon). R-12 is dichlorodifluoromethane ($CC1_2F_2$). By law, R-12 is no longer used in A/C systems. This resulted from studies showing that the earth's ozone layer was being depleted by the **chlorofluorocarbons (CFCs)** found in R-12. The ozone layer is the earth's outermost shield of protection. This delicate layer protects against harmful effects of the sun's ultraviolet rays. Because A/C systems with R-12 are susceptible to leaks, further damage to the ozone layer could be avoided by not using R-12 in A/C units.

R-134a

Of the many chemicals that could have replaced R-12, automobile manufacturers decided to use R-134a, which contains no chlorine. This refrigerant may also be referred to as SUVA. R-134a is tetrafluoroethane (CH_3CF_3) and considered a **hydrofluorocarbon (HFC)** that causes less damage to the ozone layer when released to the atmosphere. Although R-134a air conditioners operate in the same way and with the same basic components as R-12 systems, the two refrigerants are not interchangeable.

R-134a systems operate at higher pressures and are designed to handle these pressures **(Figure 54–12)**. R-134a systems also require different service techniques and equipment. All R-134a systems are identified by an underhood decal **(Figure 54–13)** and by the hoses and fittings used in the system. Service equipment for R-134a is also different. Retrofit kits are available to convert older R-12 systems to R-134a.

Although R-134a is less likely to have an adverse effect on the ozone layer, it still has the capability of contributing to the "greenhouse effect" when released into the air. The recovery and recycling of R-12 and R-134a is mandatory by law.

In 1987, many countries worldwide agreed to the Montreal Protocol agreement. This agreement began the phasing out of R-12 refrigerant. This agreement was followed up by 1990 U.S. Clean Air Act that mandated that all refrigerants were to be recovered and recycled. Section 609 of the act requires that all service technicians who work on A/C systems must be certified in proper refrigerant recovery and recycling. This section also mandates that all recovery and recycling equipment must be certified. Section 609 is a United States requirement and is not valid in other countries. Some states have stricter laws regarding refrigerant and these must be followed. While Section 609 certification is not required for purchasing R-134a, it is necessary for those who recover R-134a.

The Kyoto Protocol, a worldwide environmental program, has set standards for the reduced use of greenhouse gases, including R-134a. While not every country has signed onto the Kyoto Protocol, standards set by the European Union (EU) and the U.S. EPA have mandated the transition to a new refrigerant, one with a reduced global warming potential (GWP). As a result, some European and Japanese manufacturers began to eliminate R-134a A/C systems in 2013. This means those companies will be shipping vehicles to the United States with an alternative refrigerant and U.S. service facilities will need to be equipped to service R-134a systems and its replacement, HFO-1234yf. Full adoption of 1234yf is proposed to occur by 2017.

HFO-1234yf

The replacement for R-134a is HFO-1234yf. HFO means the refrigerant is a hydrofluoro-olefin based chemical. 1234yf differs from R-134a in that it has a GWP of 4 compared to that of 1430 for R-134a. This provides a major reduction in the impact of the refrigerant on global warming if accidentally released into the atmosphere. Another benefit to changing to 1234yf is that it can be used in existing mobile air-conditioning systems with very little change to the system as operating pressures and temperatures are very similar to R-134a.

FIGURE 54-13 A typical decal informing the technician that the system uses R-134a.

One issue with 1234yf that has caused some debate and delay in its adoption has to do with its flammability. In 2012, Daimler announced it would not use 1234yf after crash tests of its vehicles equipped with 1234yf revealed flammability issues. A potential for the refrigerant to ignite exists when the refrigerant is released in a hot engine compartment.

Alternative Refrigerants

As part of the Clean Air Act, the EPA identifies and publishes a list of acceptable and unacceptable refrigerants. This is part of the significant new alternatives policy or SNAP. In addition to refrigerants, SNAP also applies to all ozone-depleting chemicals. The list of refrigerants listed by SNAP does not mean that the EPA approves refrigerants for use in specific vehicles; it means that the refrigerant, when used as directed, is safer for humans and the environment than the R-12 refrigerant it replaces. Currently, over a dozen different types of refrigerants are approved as SNAP refrigerants for mobile air-conditioning (MAC) systems.

There are different refrigerants that can be used in automotive A/C systems; these are typically called alternative refrigerants. The EPA has a list of approved alternative refrigerants; however, the OEMs say that only R-134a should be used when retrofitting an R-12 system. The use of any refrigerant that contains flammable substances, such as propane and butane, is illegal and dangerous. Installing R-134a into an R-12 system without first removing the old refrigerant is also illegal.

CO_2 Systems

To meet the standards set up by the Kyoto Protocol, auto manufacturers need to find an alternative to R-134a. BMW and other European manufacturers have chosen CO_2 as a possible refrigerant for their A/C systems in the future. CO_2 is nontoxic when used as a refrigerant. It is known as R-744 and has a GWP of 1. The extremely low GWP means there is little environmental concern with its use. In fact, this refrigerant will not need to be recovered and recycled. If CO_2 leaks from an A/C system, the effect on the environment is very small. CO_2 is abundantly available in our air; therefore, it does not need to be manufactured.

It is claimed that CO_2-based systems will be up to 25 percent more energy efficient than the best of today's R-134a systems. In addition, CO_2 can be used for heat pump systems. Heat pump systems can supply cool and warm air and can be used in hybrid vehicles. Also, CO_2 systems need a smaller amount of gas than conventional systems, which means the size of the system is substantially less than a conventional system.

The operation of a CO_2 system is the same as that of any other A/C system but the components are different due to the higher pressures. CO_2 systems operate at pressures that are nearly ten times that of an R-134a system. CO_2 also has a critical temperature that is much lower than R-134a. Critical temperature is the temperature above which a substance cannot exist in the liquid state regardless of the pressure. Therefore, these systems need an internal heat exchanger (IHX) and accumulator. The materials used for hoses and gaskets must also be slightly different. The IHX is located between the condenser and the evaporator. The accumulator is part of the IHX **(Figure 54–14)**.

One concern about using CO_2 systems is the consequence of a leak into the passenger compartment. If a leak occurred in the evaporator, the carbon dioxide could make the cabin air toxic. Just as a CO_2 fire extinguisher displaces oxygen to put out a fire, CO_2 leaking into the passenger compartment could significantly reduce the oxygen levels inside the car. Because of this issue, CO_2 systems may require sensors to monitor cabin air quality or the A/C system could be separated into primary and secondary cooling loops. Many commercial refrigeration systems use chillers **(Figure 53–15)** so that toxic chemicals, such as ammonia, are not present in the system where humans are present. A chiller is a secondary heat exchanger that uses a less dangerous refrigerant or even an antifreeze and water mixture to cool the interior. The A/C system is used to cool the primary evaporator, which then is used to cool the secondary evaporator.

Basic Operation of an Air-Conditioning System

Refrigerants are used to carry heat from the inside of the vehicle to the outside of the vehicle. Automotive refrigerants have a low boiling point (the point at which **evaporation** occurs). For example, under atmospheric pressure, liquid R-134a boils at –15.34 °F (–26.3 °C), and becomes a vapor. As a refrigerant changes state, it absorbs a large amount of heat. Because the heat that it absorbs is from the inside of the vehicle, passengers are cooler.

To understand how a refrigerant is used to cool the interior of a vehicle, the effects of pressure and temperature must be understood first. If the pres-

sure of the refrigerant is high, so is its temperature. Likewise, if the pressure is low, so is its temperature. Therefore, the temperature of the refrigerant can be changed by changing its pressure. As the pressure on a liquid increases, its boiling point also increases. Likewise, as the pressure decreases, the boiling point of the liquid also decreases. **Figure 54–16** shows the pressures of R-134a at various temperatures.

To absorb heat, the temperature and pressure of the refrigerant are kept low. To dissipate heat, the temperature and pressure are high. As the refrigerant absorbs heat, it changes from a liquid to a vapor. As it dissipates heat, it changes from a vapor to a liquid. The change from a vapor to a liquid is called **condensation**. These two changes of state—evaporation and condensation—occur continuously as the refrigerant circulates through the system.

Refrigeration Cycle

In a basic A/C system, the heat is absorbed and transferred in the following steps **(Figure 54–17)**.

1. When the system is off, the refrigerant occupies the system as a vapor and its pressure is the same throughout the system.
2. When the A/C compressor is turned on, it increases pressure on the refrigerant and raises its temperature.
3. The refrigerant is pumped out of the compressor as a high-pressure, high-temperature vapor.
4. The high-pressure gas is sent to the condenser. Heat in the refrigerant is moved to the outside air by conduction and convection. The removal of the heat causes the refrigerant vapor to condense into a liquid under high pressure.
5. The high-pressure, high-temperature liquid leaves the bottom of the condenser and enters a receiver/dryer. The receiver/dryer removes moisture and contaminants and stores clean refrigerant until it is needed. On some systems, an accumulator is placed in line between the evaporator and compressor to capture any liquid refrigerant before it can enter the compressor.
6. The refrigerant then flows to the inlet side of the evaporator core orifice or expansion valve. These control the flow of refrigerant into the evaporator. The restriction causes the pressure and boiling point of the refrigerant to drop.
7. As the liquid refrigerant leaves the restriction, it is at its lowest pressure and temperature.

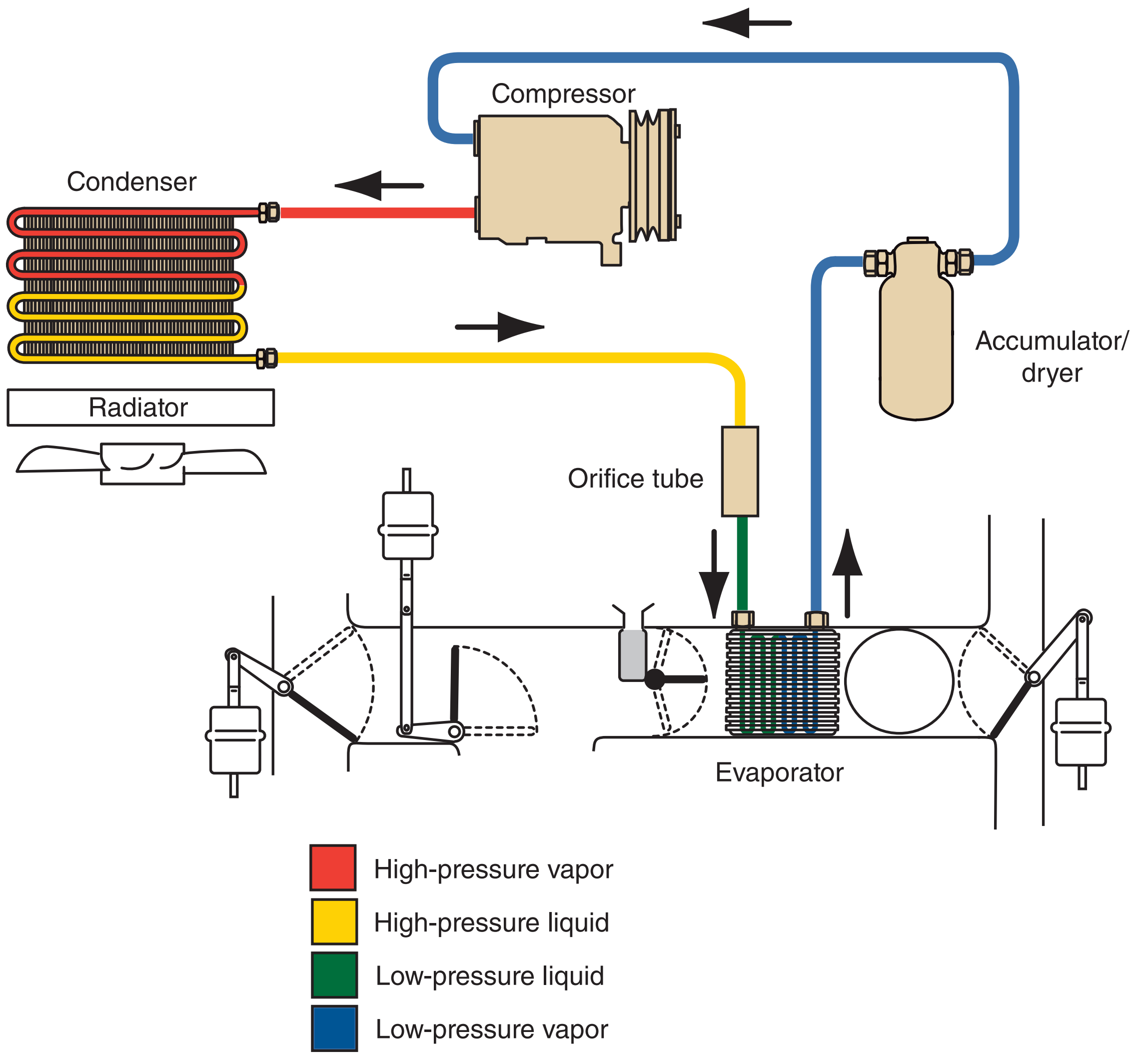

FIGURE 54-17 The basic refrigerant flow cycle.

8. The refrigerant then passes through the evaporator where it absorbs heat, through convection, from the air inside the passenger compartment. The additional heat causes the refrigerant to boil and change back to a vapor.
9. The refrigerant then returns to the compressor as a low-pressure, low-temperature vapor and the cycle continues.

An automotive A/C system is a closed, pressurized system. It consists of a compressor, condenser, receiver/dryer or accumulator, expansion valve or orifice tube, and an evaporator. To understand the operation of these components, remember that an A/C system is divided into two sides: the high side and the low side **(Figure 54–18)**. **High side** refers to the side of the system that is under high pressure and high temperature. **Low side** refers to the low-pressure, low-temperature side of the system.

Compressors

The compressor is the heart of the automotive A/C system. It separates the high and low sides of the system. The compressor is designed to pump only refrigerant vapor; liquid refrigerant will not compress and its presence in the compressor can damage it. Its primary purpose is to draw the low-pressure and low-temperature vapor from the evaporator and compress it into high-temperature, high-pressure vapor. The refrigerant then has a higher temperature than surrounding air and condenses back to a liquid form at the condenser. The secondary purpose of the compressor is to circulate or pump the refrigerant through the A/C system under the different pressures required for proper operation. The compressor is located on the engine and is typically driven

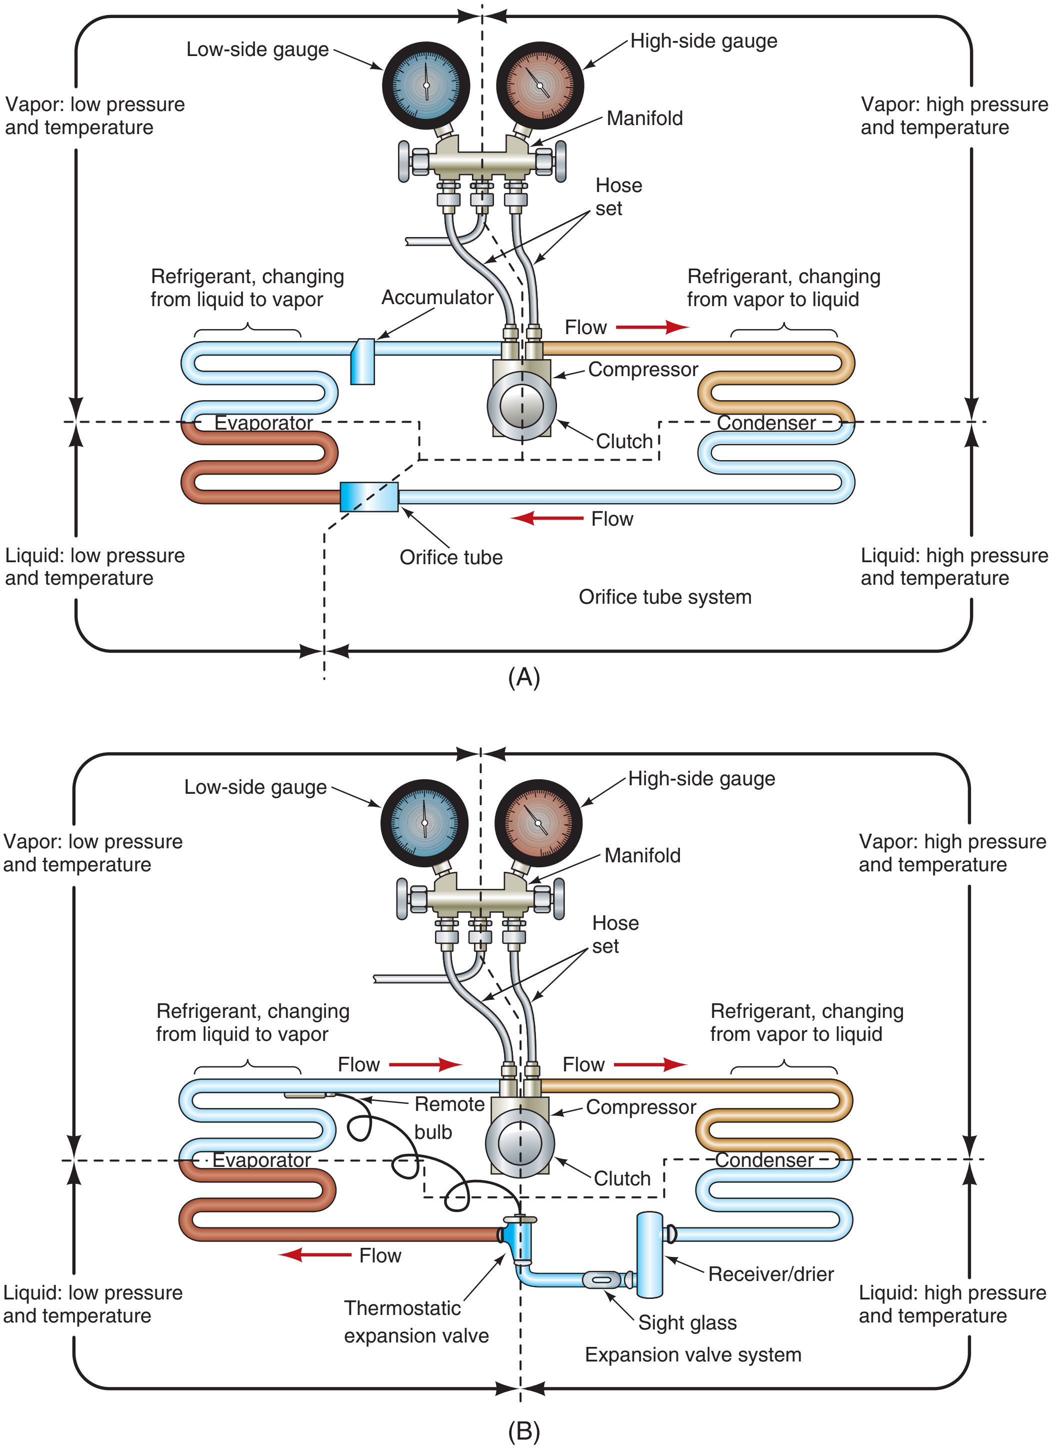

FIGURE 54–18 The low and high pressure sections of (A) an orifice tube system and (B) a system with a TXV.

by the engine's crankshaft via a drive belt. Hybrid and electric vehicles typically have a three-phase high-voltage motor in the compressor for when the engine is off.

Although there are numerous types of compressors in use today **(Figure 54–19)**, they are usually based on one of these designs.

Piston Compressor

This type of compressor **(Figure 54–20)** can have its pistons arranged in an inline, axial, radial, or V design. It is designed to have an intake stroke and a compression stroke for each cylinder. On the intake stroke, the refrigerant from the low side of the system

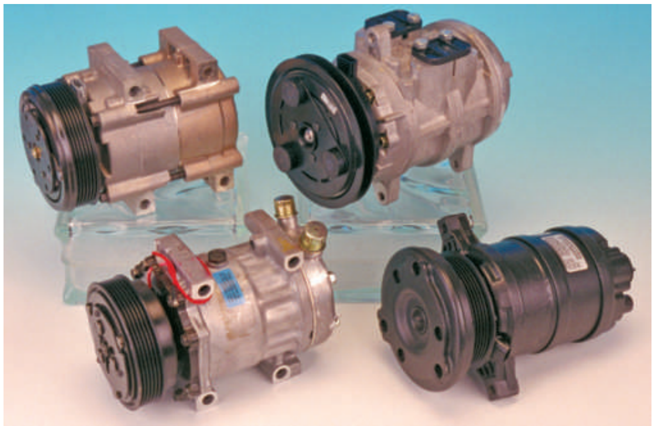

FIGURE 54–19 Various A/C compressors.

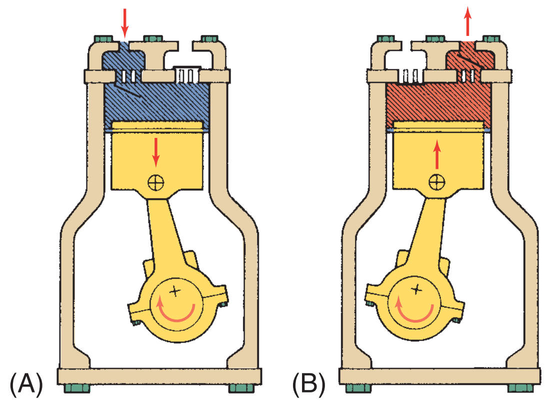

FIGURE 54–20 (A) A piston on the downstroke (intake) pulls low-pressure refrigerant into the cylinder's cavity. The intake (suction) valve is open, and the discharge valve is closed. (B) A piston on the upstroke (discharge) compresses refrigerant vapor and forces it out through the discharge valve. The intake (suction) valve is closed, and the discharge valve is open.

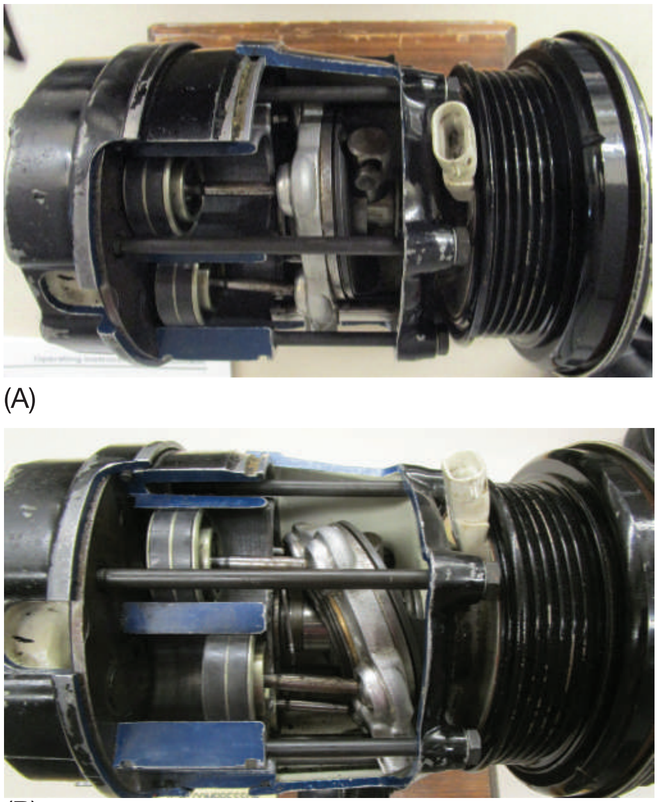
(evaporator) is drawn into the compressor. The intake of refrigerant occurs through intake reed valves **(Figure 54–21)**. These one-way valves control the flow of refrigerant vapors into the cylinder. During the compression stroke, the refrigerant vapor is compressed. This increases both the pressure and the temperature of the refrigerant. The outlet or **discharge side** reed valves then open to allow the refrigerant to move to the condenser. The outlet reed valves are the beginning of the high side of the system. Reed valves are made of spring steel, which can weaken or break if improper charging procedures are used, such as liquid charging with the engine running.

Variable Displacement Compressor Today nearly all manufacturers use variable displacement compressors **(Figure 54–22)**. These compressors are normally axial compressors, with the pistons

FIGURE 54–21 The reed valves for an A/C compressor.



(A)

(B)

arranged around and parallel to the drive shaft. The pistons are driven by a wobble plate or a swash plate. When a wobble plate is used, short pushrods connect the pistons to the plate **(Figure 54–23)**. As the compressor's drive shaft rotates, the plate wobbles and the pistons move in their bores. When a swash plate is used, it is set at an angle to the drive shaft. As the shaft rotates, the pistons move back and forth in their bores.

The angle of the wobble plate or swash plate determines the stroke of the pistons. When the stroke of the pistons is increased, more refrigerant is being pumped and there is increased cooling.

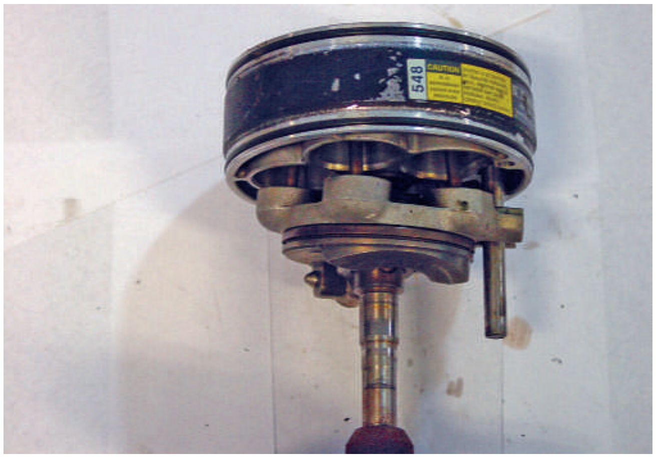

FIGURE 54–23 The pistons are driven by a short pushrod that connects the pistons to the wobble plate.

The angle is controlled by the difference in pressure between the outlet and inlet of the compressor. When the pressure inside the compressor increases, that pressure works on the bottom of the pistons and moves them closer to the cylinder head. This action shortens their stroke, thereby decreasing the displacement of the pump. As pressure inside the compressor decreases, spring tension overcomes the pressure and the pistons move down in their bores. This causes the plate angle to increase, resulting in increased stroke and displacement.

Some swash plate compressors use a solenoid control valve that opens and closes to adjust the inlet to the compressor. Controlling the suction side of the compressor changes the volume capacity and pressure. The change in pressure also affects the angle of the swash plate.

On some vehicles, the compressor does not have a clutch, which means the compressor runs constantly. These units have an electrically controlled rotary valve at the rear of the compressor to control the flow of refrigerant into a special chamber that changes the angle of the swash plate. This regulates the flow of refrigerant by changing the stroke of the pistons.

Rotary Vane Compressor

The rotary vane compressor does not have pistons. It has a rotor with several vanes and a carefully shaped housing. The sliding vanes seal against the housing at both ends. As the compressor shaft rotates, the vanes and housing form chambers. As the rotor turns, the size of the chambers changes.

The refrigerant is drawn into the chambers through the suction port. The discharge port is located at the point where the gas is completely compressed. No sealing rings are used in a vane compressor. The vanes are sealed against the housing by centrifugal force and lubricating oil. The oil sump is located on the discharge side, so the high pressure tends to force it around the vanes into the low-pressure side. This action ensures continuous lubrication. Because this type of compressor depends on a good oil supply, it is subject to damage if the system charge is lost. A protection device is used to disengage the clutch if pressure drops too low.

Scroll-Type Compressor

The scroll-type compressor has a movable scroll and a fixed or nonmovable scroll that provide an eccentric-like motion. As the compressor's crankshaft rotates, the movable scroll forces the refrigerant against the fixed scroll and toward the center of the compressor. This motion pressurizes the refrigerant. The action of a scroll-type compressor can be compared to that of a tornado. The pressure of air moving in a circular pattern increases as it moves toward the center of the circle **(Figure 54–24)**. A delivery port is positioned at the center of the compressor and allows the high-pressure refrigerant to flow into the A/C system. These compressors do not have a suction valve. They are smaller and operate more smoothly than other designs.

Compressor Clutches

Most compressors are equipped with an electromagnetic clutch as part of the compressor pulley assembly **(Figure 54–25)**. It is designed to engage the pulley to the compressor shaft when the clutch coil is energized. The purpose of the clutch is to transmit power from the engine to the compressor and to provide a means of engaging and disengaging the refrigeration system from engine operation. The clutch is driven by power from the engine's crankshaft, which is transmitted through one or more belts (a few use gears) to the pulley, which is in operation whenever the engine is running. When the clutch is engaged, power is transmitted from the pulley to the compressor shaft by the clutch drive plate. When the clutch is not engaged, the compressor shaft does not rotate, and the pulley freewheels.

The clutch allows the A/C system to be controlled by an electric circuit. The clutch relay is controlled by a temperature signal from the evaporator and a pressure switch in the refrigerant line. In most systems, the compressor clutch cycles on and off periodically

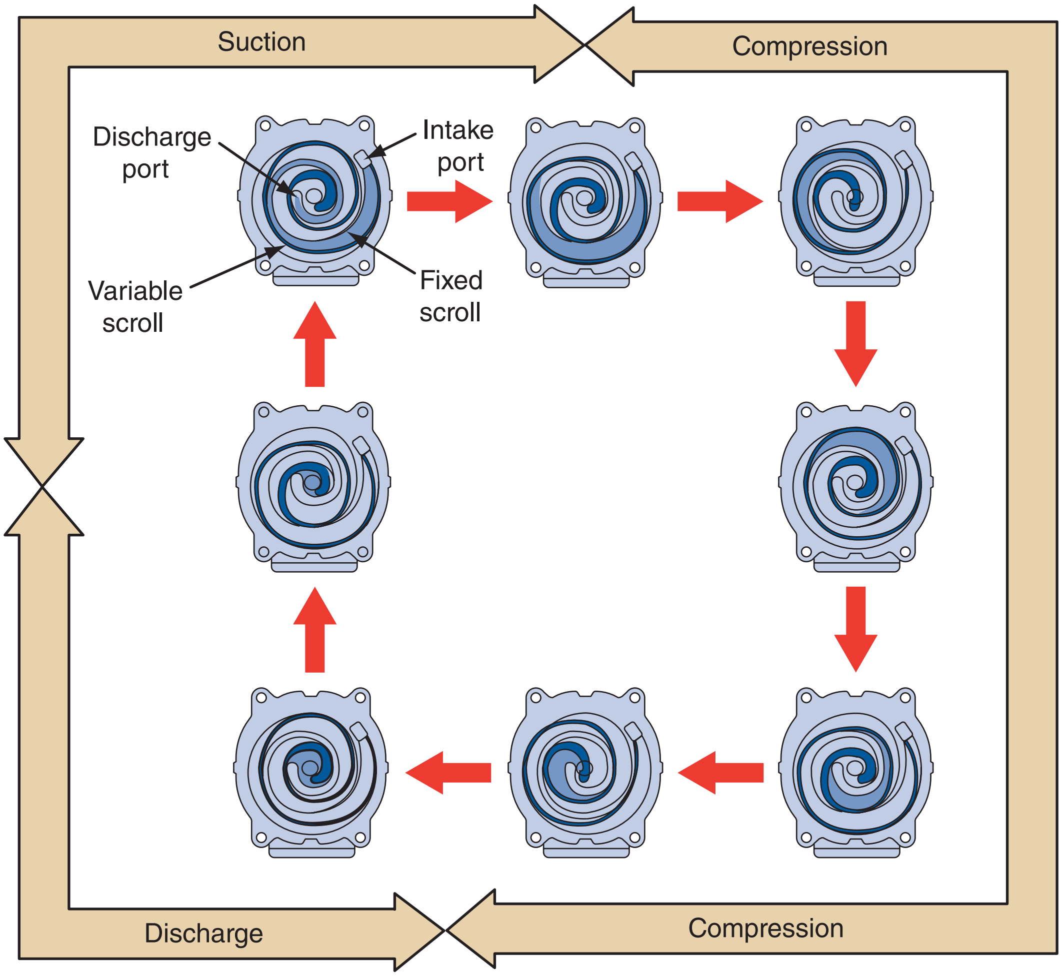

FIGURE 54–24 A scroll compressor passes through three distinct phases: suction, compression, and discharge.

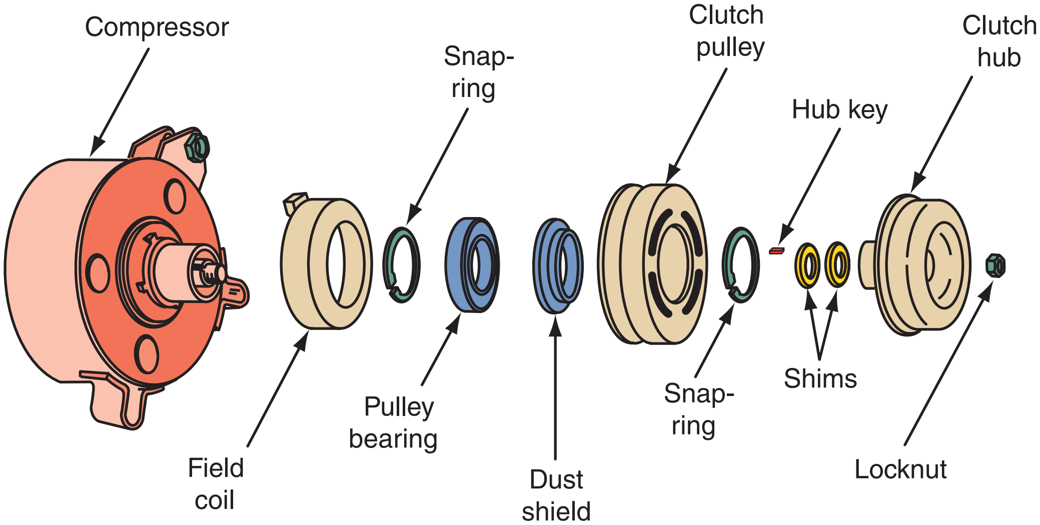

FIGURE 54–25 An A/C compressor clutch assembly.

to allow the evaporator to warm up during periods of high cooling demand.

The clutch is engaged by a magnetic field and disengaged by springs when the magnetic field is broken. When the controls call for compressor operation, the electrical circuit to the clutch is completed, the magnetic clutch is energized, and the clutch engages the compressor. When the electrical circuit is opened, the clutch disengages the compressor. Many systems use a diode wired in parallel with the compressor clutch to absorb voltage spikes when the clutch disengages. Voltage spikes are possible as the magnetic field that holds the clutch engaged collapses once the circuit is open. If left unchecked, the voltage spike could damage the electronics controlling clutch operation.

Modern clutches use a stationary clutch coil. When the system is turned on, the pulley assembly is magnetized by the stationary coil on the compressor body, thus engaging the clutch to the clutch hub attached to the compressor shaft. This activates the A/C system. Depending on the system, the magnetic clutch is usually pressure controlled to cycle the operation of the compressor (depending on system temperature or pressure). In some system designs, the clutch might operate continually when the system is turned on.

Clutchless Compressors

Some late-model A/C systems use clutchless or variable drive compressors. Clutchless systems control refrigerant flow through the compressor by varying swash plate angle with a pulse width modulated control solenoid. The climate control module uses input data such as cabin temperature, ambient temperature, evaporator temperature, engine speed, and system pressures to determine the required flow through the compressor. When the system is off or cooling is not needed, the solenoid limits swash plate angle from 2 to 3 percent. As cooling load increases, swash plate angle is increased up to 100 percent.

Electric Drive Compressors

One of the features of hybrid and other new vehicles is the idle-stop or stop-start system. When the vehicle is sitting at a light, the system shuts down the engine. This means there is no power to drive the A/C compressor. Therefore, most hybrid vehicles have an electric drive for the compressor. An electric motor is built into the compressor and is powered by the vehicle's high-voltage system **(Figure 54–26)**. This means the A/C system can operate when the engine is not running.

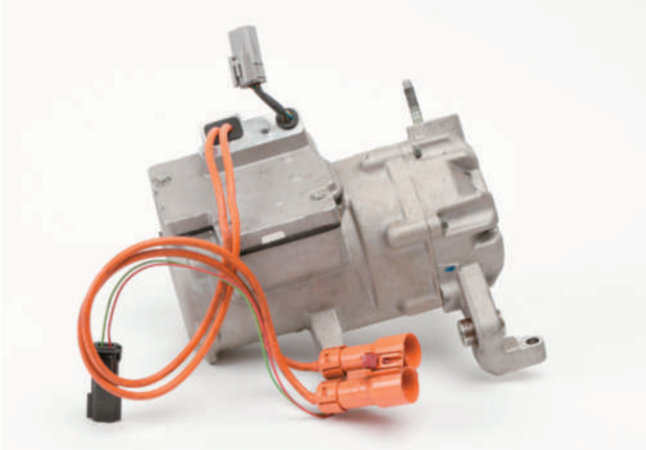

FIGURE 54–26 An electric A/C compressor.

A/C compressors in hybrid vehicles are typically identical to those used in a conventional vehicle, except for the portion that is actuated by the electric motor. Because the compressor is energized by electricity, the control module can control its speed. This enables the system to provide ideal cooling while using a minimum of energy to run the system.

In most cases, the compressor's motor is driven by AC voltage from the vehicle's inverter. The system controls the voltage to rotate the compressor at a desired speed. This speed is calculated by the control module and is based on a target evaporator temperature and the actual evaporator temperature.

The Accord hybrid is also equipped with a dual-scroll "hybrid" A/C compressor **(Figure 54–27)**. The A/C system uses two compressors built into a single housing; one compressor is driven by the engine and the other is driven by an electric motor powered by the high-voltage battery. A driver circuit in the control module provides switched high voltage to the motor. The action of the driver is determined by inputs from the climate control settings and the CAN bus. The mechanically driven side uses a normal electric clutch controlled by the climate control module. The electrically driven side uses a high-voltage, brushless, three-phase motor driven by a controller. When full cooling is needed, the A/C unit relies on both power sources to provide maximum cooling. During normal cooling, the A/C is powered by either the belt-driven compressor or the electric motor-driven compressor.

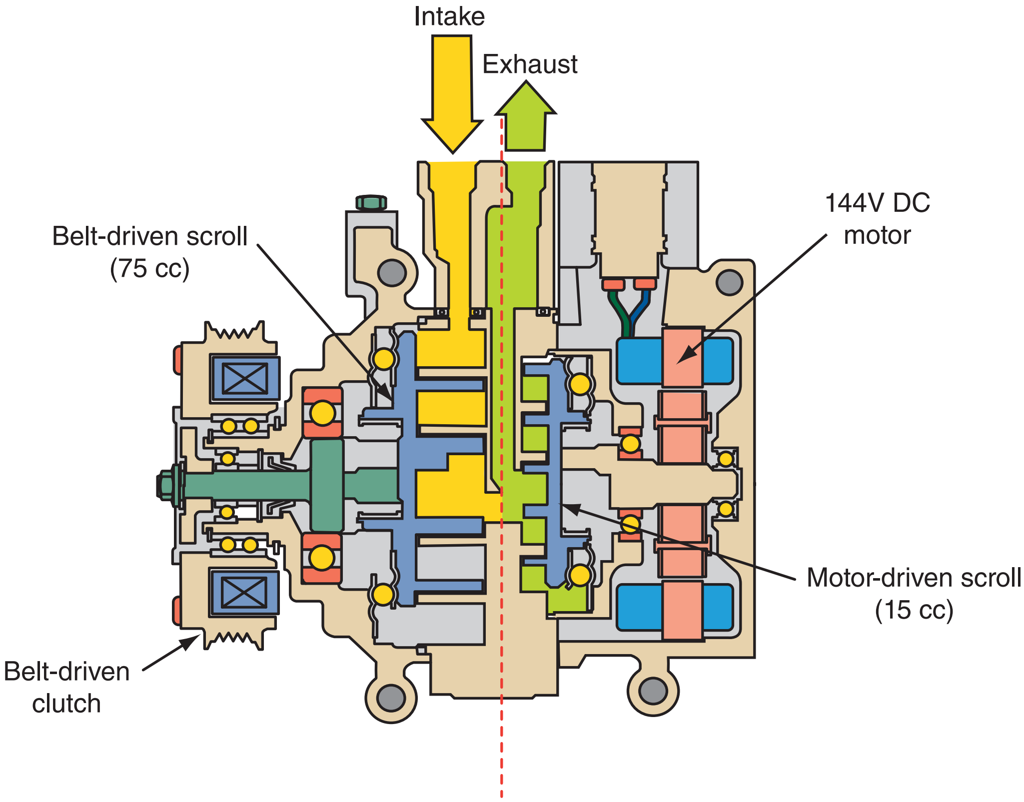

FIGURE 54–27 A dual-scroll A/C compressor powered by a drive belt and/or an electric motor.

Refrigerant Oils

Normally the only source of lubrication for a compressor is the oil mixed with the refrigerant. A/C systems carry oil through the system with the refrigerant to lubricate the parts of the system, including the compressor. Because of the loads and speeds at which the compressor operates, proper lubrication is a must for long compressor life.

The refrigerant oil required by the system depends on a number of things, but it is primarily dictated by the refrigerant used in the system. R-12 systems used a mineral oil. Mineral oil, however, cannot be used with R-134a. R-134a systems require a synthetic oil, polyalkaline glycol (PAG) or POE (polyester) oil. Most manufacturers use PAG oil in R-134a systems. Aftermarket companies, on the other hand, often choose ester oils for lubrication with R-134a because they tend to attract less moisture than PAG oils. Most often when a system has been converted from R-12 to R-134a, ester oil will be recommended. Ester oil mixes well with mineral oil because it is hydrocarbon based.

There are a number of different blends of refrigerant oil; always use the one recommended by the vehicle manufacturer or compressor manufacturer. Failure to use the correct oil will cause damage to the compressor.

Warning! Hybrid vehicles often have an electrically driven compressor. Because the electric motor is inside the compressor case and is in contact with the oil in the compressor, only the specified oil should be used in the compressor. This oil has electrical insulating qualities that protect you from dangerous electrical shocks. Also, if you use the wrong oil, the A/C unit will be contaminated and this may result in a need to replace the compressor, condenser, evaporator, and/or all of the refrigerant lines.

Condenser

The condenser **(Figure 54–28)** consists of coiled refrigerant tubing mounted in a series of thin cooling fins to provide maximum heat transfer in a minimum amount of space. The condenser is normally mounted just in front of the vehicle's radiator. It receives the full

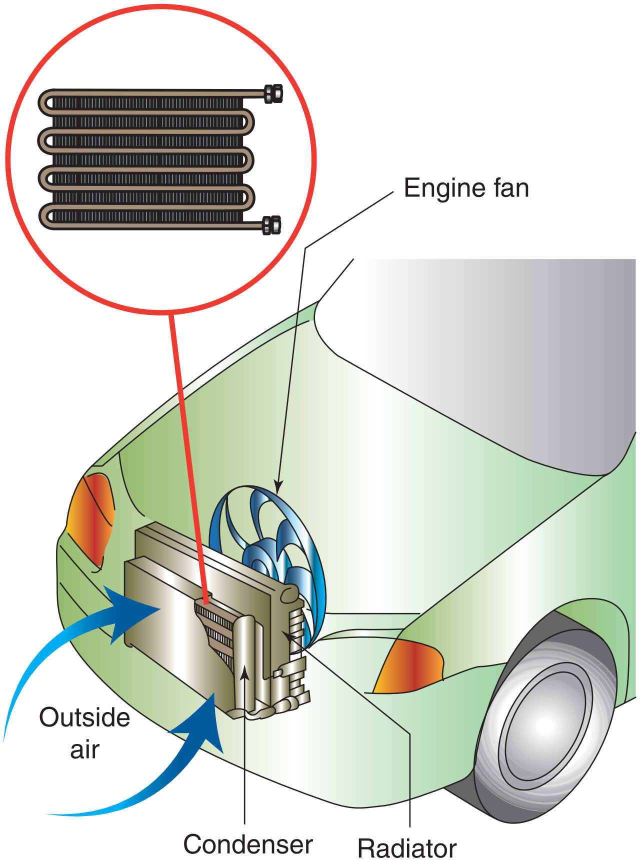

FIGURE 54–28 A typical condenser.

flow of ram air from the movement of the vehicle or airflow from the radiator fan or dedicated condenser fan when the vehicle is standing still.

The purpose of the condenser is to condense or liquefy the high-pressure, high-temperature vapor coming from the compressor. To do so, it must give up its heat. The condenser receives very hot (normally 200 to 400 °F), high-pressure refrigerant vapor from the compressor through its discharge hose. The refrigerant vapor enters the inlet at the top of the condenser and as the hot vapor passes down through the condenser coils, heat (following its natural tendencies) moves from the hot refrigerant into the cooler air as it flows across the condenser coils and fins. This process causes a large quantity of heat to be transferred to the outside air and the refrigerant to change from a high-pressure hot vapor to a high-pressure warm liquid. This high-pressure warm liquid flows from the outlet at the bottom of the condenser through a line to the receiver/dryer or to the refrigerant metering device if an accumulator is used instead of a dryer.

In an A/C system operating under an average heat load, the condenser has a combination of hot refrigerant vapor in the upper two-thirds of its coils. The lower third of the coils contains the warm liquid refrigerant, which has condensed. This high-pressure, liquid refrigerant flows from the condenser and on toward the evaporator. In effect, the condenser is a true heat exchanger.

Subcoolers and Internal Heat Exchangers

Some vehicles have a subcooler built into the condenser or have a separate subcooler. Subcooling is a process by which sensible heat is removed from liquid refrigerant, resulting in lower refrigerant temperatures. Sensible heat is heat that can be felt and measured and represents the energy required to change the temperature of a substance without causing a change in its state. The separate subcooler is located between the condenser and evaporator. A subcooler is a heat exchanger that allows the refrigerant to lose additional heat after it becomes a liquid. The subcooler increases the efficiency of the system by cooling the refrigerant and prevents premature vaporization or flash off as the refrigerant passes through the expansion valve and before it reaches the evaporator. Premature flash off can result in stopping some of the refrigerant from evaporating, and that part of the refrigerant would have no useful effect on the cooling of the vehicle. The heat exchanger causes the liquid to be subcooled to a level that ensures little or no flash gas on its way to the evaporator.

Many vehicles have a condenser with a subcool chamber **(Figure 54–29)**. In these condensers, refrigerant enters at the top as a high-pressure gas. It then passes through a receiver/dryer or modulator to separate the liquid from the gaseous refrigerant. The modulator contains a desiccant and filter to remove the moisture and foreign material from the refrigerant. After passing through the modulator, the refrigerant flows into the bottom subcooler chamber to further cool the liquid. This results in complete liquidization of the refrigerant and better A/C performance. These condensers have thin tubes and low fin height, which improve the heat exchange rate. Because of this two-step approach, the refrigerant sent to the evaporator is almost completely liquefied.

R-1234yf systems and some R-134a systems use an internal heat exchanger (IHX). The IHX is a liquid-to-vapor heat exchanger that looks like a pipe within a pipe **(Figure 54–30)**. Hot liquid refrigerant from the condenser flows through the inner pipe, which is surrounded by cool refrigerant from the outlet of the evaporator. Surrounding the hot liquid with the cooler gas removes heat from the liquid, subcooling it beyond what was achieved by the condenser. This improves overall system efficiency and improves performance.

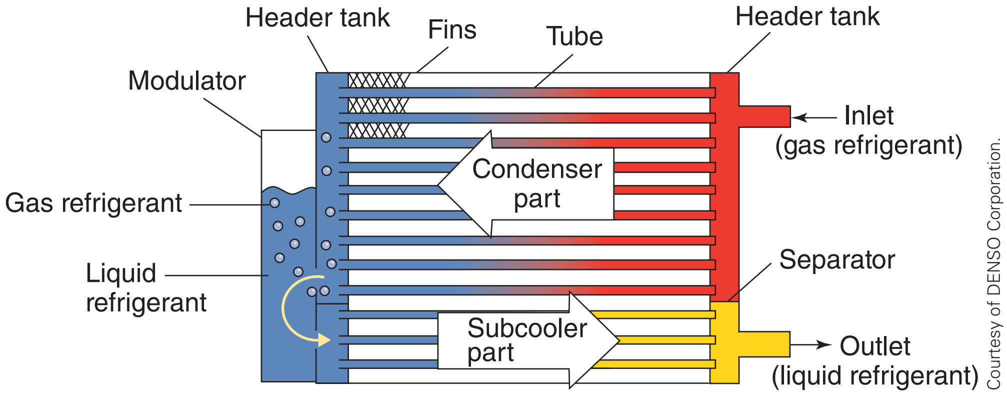

FIGURE 54–29 A condenser with a built-in subcooler.

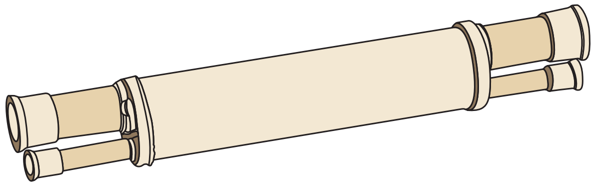

FIGURE 54–30 An internal heat exchanger.

FIGURE 54–31 Two different accumulator designs.

Receiver/Dryer

Used on many systems, the receiver/dryer is a storage tank for the liquid refrigerant from the condenser, which flows into the upper portion of the receiver tank containing a bag of desiccant (moisture-absorbing material such as silica alumina or silica gel). As the refrigerant flows through an opening in the lower portion of the receiver, it is filtered through a mesh screen attached to a baffle at the bottom of the receiver. The purpose of the desiccant in this assembly is to absorb any moisture present that might enter the system during assembly. These features of the assembly prevent obstruction to the valves or damage to the compressor.

Depending on the manufacturer, the receiver/dryer may be known by other names such as filter or dehydrator. Regardless of its name, the function is the same. Included in many receiver/dryers are additional features such as a high-pressure fitting, a pressure relief valve, and a sight glass for determining the state and condition of the refrigerant in the system.

Accumulator

Most late-model systems are not equipped with a receiver/dryer; rather, they use an accumulator to accomplish the same thing **(Figure 54–31)**. The accumulator is connected into the low side at the outlet of the evaporator. The accumulator also contains a desiccant and is designed to store excess refrigerant and to filter and dry the refrigerant **(Figure 54–32)**. If liquid refrigerant flows out of the evaporator, it will be collected by and stored in the accumulator. The main purpose of an accumulator is to prevent liquid from entering the compressor.

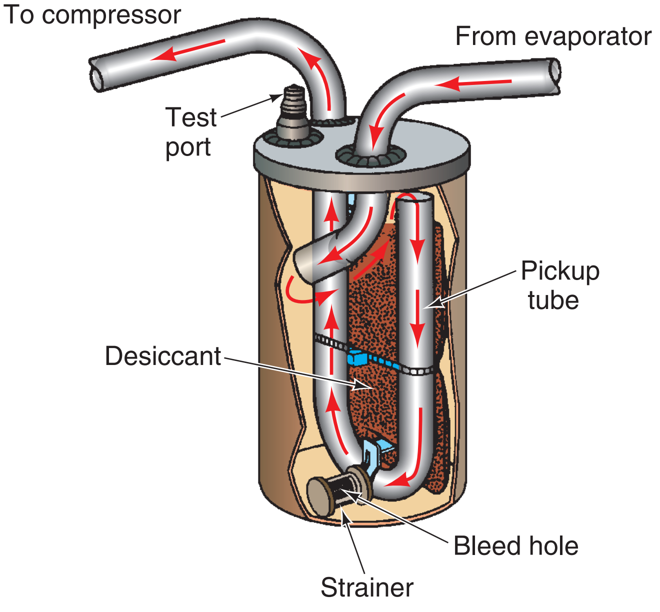

FIGURE 54–32 An accumulator/dryer.

Thermostatic Expansion Valve/ Orifice Tube

The refrigerant flow to the evaporator must be controlled to obtain maximum cooling while ensuring complete evaporation of the liquid refrigerant within the evaporator. This is accomplished by a thermostatic expansion valve (TEV or TXV) or a fixed orifice tube.

The TEV is mounted at the inlet to the evaporator and separates the high-pressure side of the system from the low-pressure side. The TEV regulates refrigerant flow to the evaporator to prevent evaporator flooding or starving. In operation, the TEV regulates the refrigerant flow to the evaporator by balancing the inlet flow to the outlet temperature.

Both externally and internally equalized TEVs are used in A/C systems. The only difference between the two valves is that the external TEV uses an equalizer line connected to the evaporator outlet line as a means of sensing evaporator outlet pressure. The internal TEV senses evaporator inlet pressure through an internal equalizer passage. Both valves have a capillary tube to sense evaporator outlet temperature. The tube is filled with a gas, which, if allowed to escape due to careless handling, will ruin the TXV.

During stabilized conditions, the pressure on the bottom of the expansion valve diaphragm becomes equal to the pressure on the top of the diaphragm. This allows the valve spring to close the valve. When the system is started, the pressure on the bottom of the diaphragm drops rapidly, allowing the valve to open and meter liquid refrigerant to the lower evaporator tubes where it begins to vaporize **(Figure 54–33)**.

Compressor suction draws the vaporized refrigerant out of the top of the evaporator at the top tube, where it passes by the sealed sensing bulb. The bottom of the valve diaphragm internally senses the evaporator pressure through the internal equalization passage around the sealed sensing bulb. As evaporator pressure is increased, the diaphragm flexes upward, pulling the pushrod away from the ball seat of the expansion valve. The expansion valve spring forces the ball onto the tapered seat and the liquid refrigerant flow is reduced.

As the pressure is reduced due to restricted refrigerant flow, the diaphragm flexes downward again, opening the expansion valve to provide the required controlled pressure and refrigerant flow condition. As the cool refrigerant passes by the body of the sensing bulb, the gas above the diaphragm contracts and allows the expansion valve spring to close the expansion valve. When heat from the passenger compartment is absorbed by the refrigerant, it causes the gas to expand. The pushrod again forces the expansion valve to open, allowing more refrigerant to flow so that more heat can be absorbed.

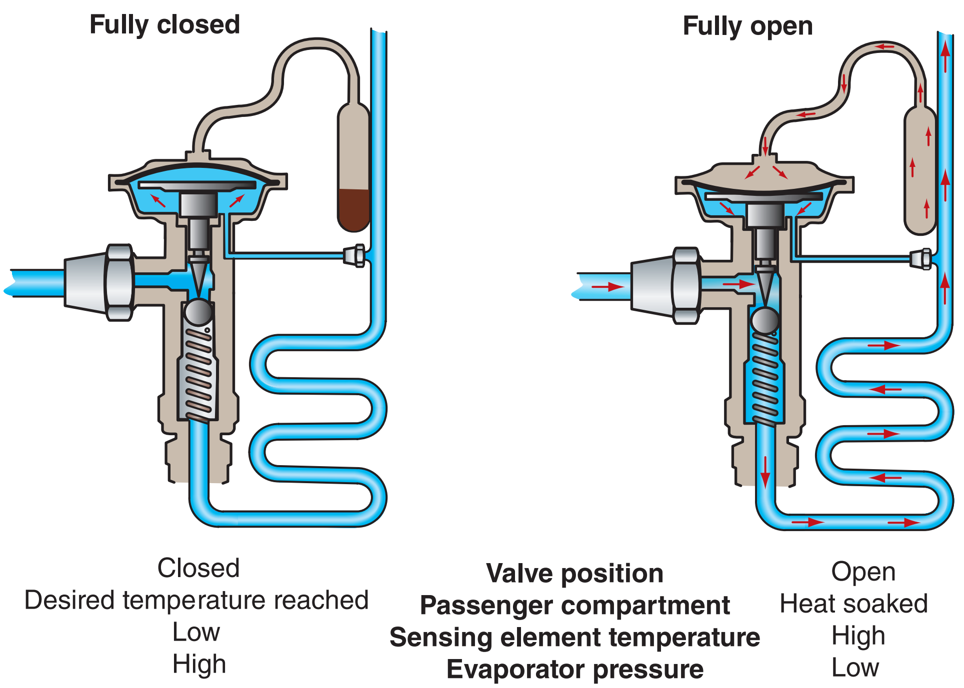

FIGURE 54–33 How a TXV regulates refrigerant flow through the evaporator.

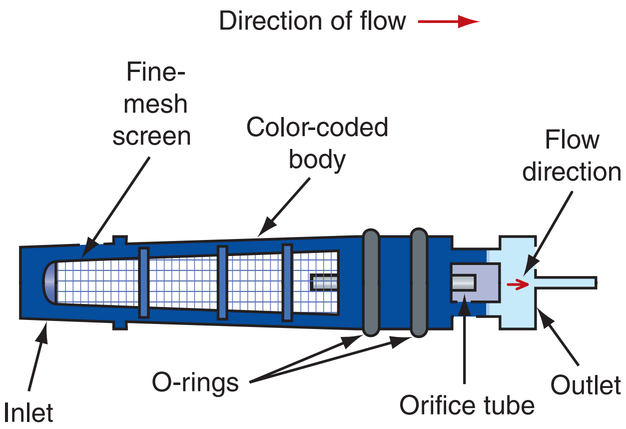

FIGURE 54–34 A typical orifice expansion tube.

Orifice Tube

Like the TEV, the orifice tube is the dividing point between the high- and low-pressure parts of the system. However, its metering or flow rate control does not depend on comparing evaporator pressure and temperature. It is a fixed orifice **(Figure 54–34)**. The flow rate is determined by pressure difference across the orifice and by subcooling at the bottom of the condenser. Because an orifice tube cannot vary the flow rate itself, it is used with a cycling clutch compressor. The compressor turns on and off to control flow through the system. Orifice tubes have been phased out in modern systems that use variable displacement compressors.

H-Block Thermal Expansion Valve

Many newer vehicles use an H-block TXV. The H-block is located near the firewall and close to the evaporator and has four separate line connections: one to and one from the evaporator, one that returns to the compressor, and one from the condenser **(Figure 54–35)**. The outlet from the evaporator passes over the sensing element in the H-block. If the outlet temperature is high, it causes the sensing element to allow more refrigerant flow to the evaporator. If the temperature of the outlet gas is low, flow is reduced.

Evaporator

The evaporator, like the condenser, consists of a refrigerant coil mounted in a series of thin cooling fins **(Figure 54–36)**. It provides a maximum amount of heat transfer in a minimum amount of space. The evaporator is usually located beneath the dashboard or instrument panel.

Upon receiving the low-pressure, low-temperature liquid refrigerant from the TEV or orifice tube in the form of an atomized (or droplet) spray, the evaporator serves as a boiler or vaporizer. This regulated flow of refrigerant boils immediately. Heat from the core surface is lost to the boiling and vaporizing refrigerant, which is cooler than the core, thereby

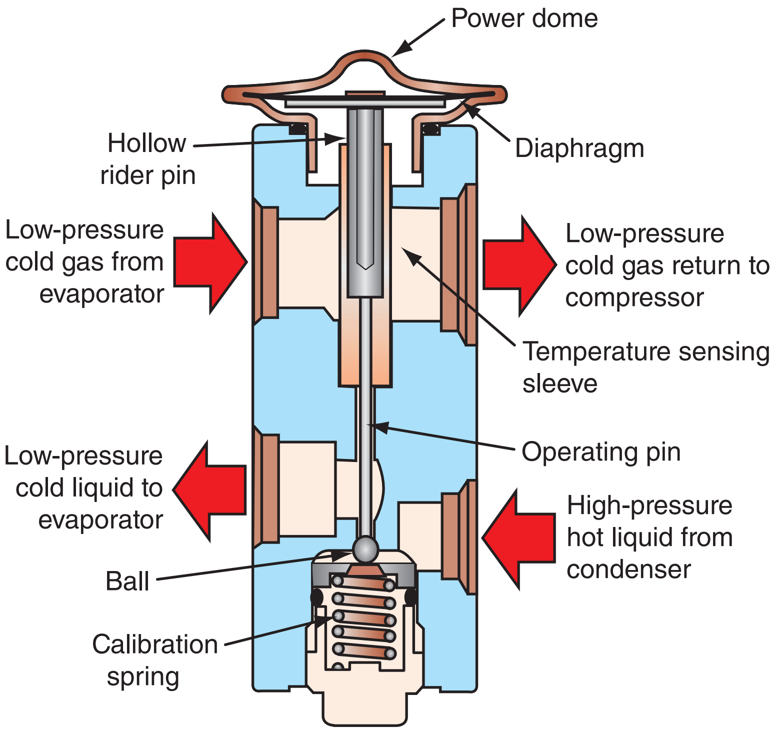

FIGURE 54–35 An H-block expansion valve.

FIGURE 54-36 A typical evaporator.

cooling the core. The air passing over the evaporator loses its heat to the cooler surface of the core, thereby cooling the air inside the car. As the process of heat loss from the air to the evaporator core surface is taking place, any moisture (humidity) in the air condenses on the outside of the evaporator core and is drained off as water. A drain tube in the bottom of the evaporator housing leads the water outside the vehicle **(Figure 54–37)**. This dehumidification of air is an added feature of the A/C system that adds to passenger comfort. It also is used as a means of controlling fogging of the vehicle windows. Under certain conditions, however, too much moisture can accumulate on the evaporator coils. An example would be when humidity is extremely high and the maximum cooling mode is selected. The evaporator temperature might become so low that moisture would freeze on the evaporator coils before it can drain off.

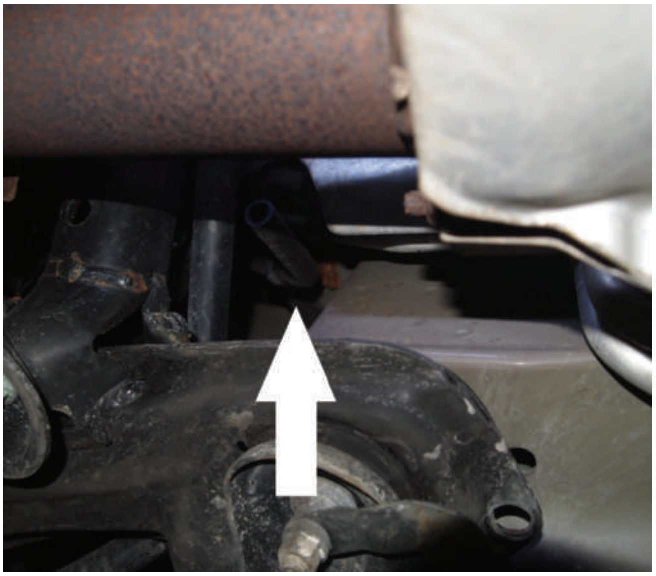

FIGURE 54-37 An evaporator drain.

Through the metering, or controlling, action of the TEV or orifice tube, greater or lesser amounts of refrigerant are provided in the evaporator to adequately cool the car under all heat load conditions. If too much refrigerant is allowed to enter, the evaporator floods. This results in poor cooling due to the higher pressure (and temperature) of the refrigerant. The refrigerant can neither boil away rapidly nor vaporize. On the other hand, if too little refrigerant is metered, the evaporator starves. Poor cooling again results because the refrigerant boils away or vaporizes too quickly before passing through the evaporator.

The temperature of the refrigerant vapor at the evaporator outlet will be approximately 4 to 16 °F higher than the temperature of the liquid refrigerant at the evaporator inlet. This temperature differential ensures that the vapor will not contain any droplets of liquid refrigerant that would be harmful to the compressor.

Blower Motor/Fan

The blower motor/fan assembly is located in the evaporator housing. Its purpose is to increase airflow in the passenger compartment. The blower motor, which is the same as those used in heater systems, draws warm air from the passenger compartment, forces it over the coils and fins of the evaporator, and blows the cooled, cleaned, and dehumidified air into the passenger compartment. The blower motor is controlled by a fan switch. On some systems, blower speed is regulated by the speed of the compressor.

Refrigerant Lines

All of the major components of the system have inlet and outlet connections that accommodate either flare or O-ring fittings. The refrigerant lines that connect between these units are made up of an appropriate length of hose or tubing with flare or O-ring fittings at each end as required **(Figure 54–38)**. In either case the hose or tube end of the fitting is constructed with sealing beads to accommodate a hose or tube clamp connection.

There are three major refrigerant lines. Suction lines are located between the outlet side of the evaporator and the inlet side or suction side of the

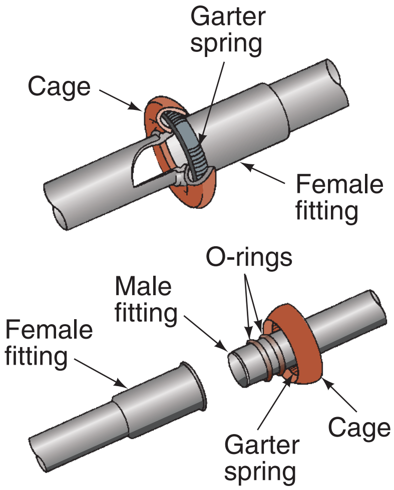

FIGURE 54–38 Spring-lock line coupler with O-rings.

compressor. They carry the low-pressure, low-temperature refrigerant vapor to the compressor where it again is recycled through the system. Suction lines are always distinguished from the discharge lines by touch and size. During operation, they are cold to the touch. The suction line is also larger in diameter than the discharge line.

Beginning at the discharge outlet on the compressor, the discharge or high-pressure line connects the compressor to the condenser. The liquid lines connect the condenser to the receiver/dryer and the receiver/dryer to the inlet side of the expansion valve. Through these lines, the refrigerant travels in its path from a gas state (compressor outlet) to a liquid state (condenser outlet) and then to the inlet side of the expansion valve, where it vaporizes on entry to the evaporator. Discharge and liquid lines are very warm to the touch when the system is operating and easily distinguishable from the suction lines.

Aluminum tubing is commonly used to connect A/C components where flexibility is not required. Where the line is subjected to vibrations, special rubber hoses are used. Typically the compressor outlet and inlet lines are rubber hoses with aluminum ends and fittings.

R-134a and R-1234yf systems must have quick-disconnect service fittings throughout the system **(Figure 54–39)**. The two systems have similar looking service fittings but they are different and not interchangeable. These also have hoses specially made for R-134a. They have an additional layer of rubber that serves as a barrier to prevent the refrigerant from escaping through the pores of the hose. Some late-model R-12 systems also use these barrier hoses to prevent the loss of refrigerant through the walls of the hoses.

Air-Conditioning Systems and Controls

There are two basic types of automotive air-conditioning systems. They are classified according to the method used in obtaining temperature control and are known as cycling clutch systems or evaporator pressure or temperature control systems.

Evaporator Pressure Control System

Evaporator controls maintain a backpressure in the evaporator. Because of the refrigerant temperature/pressure relationship, the effect is to regulate evaporator temperature. The temperature is controlled to a point that provides effective air cooling but prevents the freezing of moisture that condenses on the evaporator.

In this type of system, the compressor operates continually when dash controls are in the air-conditioning position. Evaporator outlet air temperature is automatically controlled by an evaporator pressure control valve. This type of valve throttles the flow of refrigerant out of the evaporator as required to establish a minimum evaporator pressure and thereby prevent freezing of condensation on the evaporator core.

Cycling Clutch System

In every **cycling clutch** system, the compressor is run intermittently by means of controlling the application and release of its clutch through a thermostatic or pressure switch. The thermostatic switch senses the evaporator's outlet air temperature through a capillary tube that is part of the switch assembly. With a high sensing temperature, the thermostatic switch is closed and the compressor clutch is energized. As the evaporator outlet temperature drops to a preset level, the thermostatic switch opens the circuit to the compressor clutch. The compressor then ceases to operate until such time as the evaporator temperature rises above the switch setting. From this on-and-off operation is derived the term *cycling clutch*. In effect, the thermostatic switch is calibrated to allow the lowest possible evaporator outlet temperature that would prevent the freezing of condensation that might form on the evaporator.

Variations of the cycling clutch system include a system with a thermostatic expansion valve and a system with an orifice tube.

Cycling Clutch System with Thermostatic Expansion Valve Some factory installations utilize a cycling clutch system that incorporates a TEV and receiver/dryer, as do some add-on units. The evaporator and control components are either in the engine compartment or an integral part of the cowl. In such cases there is a common blower and duct work for both heating and air-conditioning purposes. Also in these installations, the thermostatic switch has no temperature control knob and is usually mounted on the evaporator or its case. Temperature control is accomplished by using fresh or recirculating air and by reheating the cooled air in the heater core. The clutch cycles only to prevent evaporator icing.

Cycling Clutch System with Orifice Tube (CCOT) A typical CCOT system is illustrated in **Figure 54–40**. The system is factory installed and can use a thermostatic clutch cycling switch mounted on the evaporator case or a pressure cycling switch located on the accumulator. An expansion (orifice) tube is used in place of the TEV. Also, the system has an accumulator in the evaporator outlet. The accumulator is used primarily to separate vapor from liquid refrigerant before it enters the compressor. It also contains a drying agent or desiccant to remove moisture. The CCOT system has no receiver/dryer or sight glass. This system does have a special orifice, the oil bleed orifice, that allows refrigerant oil to return to the compressor rather than to collect in the accumulator.

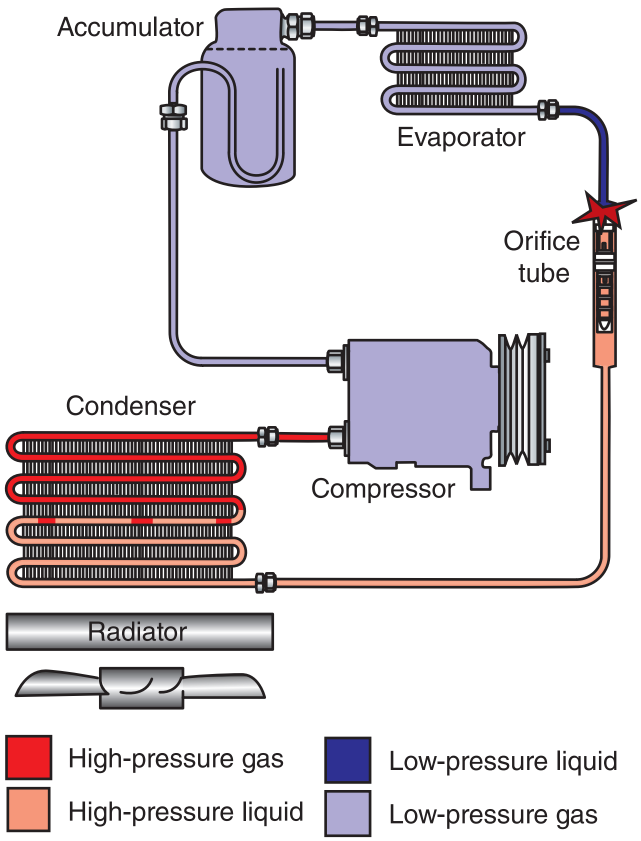

FIGURE 54–40 A typical cycling clutch system with an expansion (orifice) tube.

Compressor Controls

Many controls are used to monitor and trigger the compressor during its operational cycle. Each of these represents the most common protective control devices designed to ensure safe and reliable operation of the compressor.

Ambient Temperature Switch This switch senses outside air temperature and is designed to prevent compressor clutch engagement when air conditioning is not required or when compressor

operation might cause internal damage to seals and other parts.

The switch is in series with the compressor clutch electrical circuit and closes at about 37 °F (2.7 °C). At all lower temperatures, the switch is open, preventing clutch engagement.

On some vehicles, the ambient switch is located in the air inlet duct of air-conditioning systems regulated by evaporator pressure controls; other makes have it installed near the radiator. It is not required on systems with a thermostatic or pressure switch.

Thermostatic Switch In cycling clutch systems, the thermostatic switch is placed in series with the compressor clutch circuit so it can turn the clutch on or off. It has two purposes. It de-energizes the clutch and stops the compressor if the evaporator is at the freezing point **(Figure 54–41)**.

When the temperature of the evaporator approaches the freezing point (or the low setting of the switch), the thermostatic switch opens the circuit and disengages the compressor clutch. The compressor remains inoperative until the evaporator temperature rises to the preset temperature, at which time the switch closes and compressor operation resumes.

Evaporator Temperature Sensor

Many systems use temperature sensors or thermistors to determine evaporator temperature. This information is used to help control refrigerant flow to prevent freezing the evaporator.

Pressure Cycling Switch This switch is electrically connected in series with the compressor electromagnetic clutch. Like the thermostatic switch, the turning on and off of the pressure cycling switch controls the operation of the compressor.

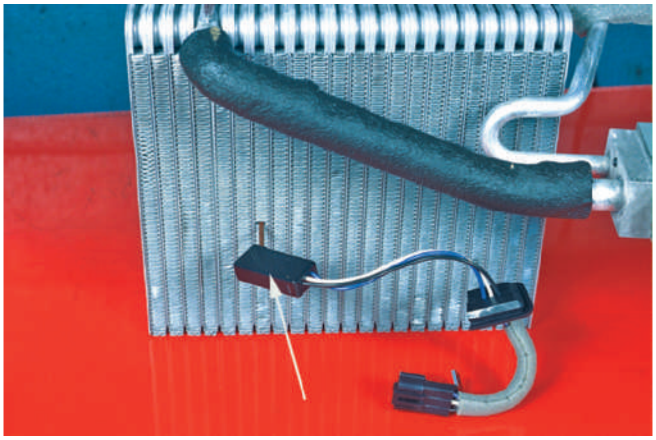

FIGURE 54-41 A temperature sensor mounted onto an evaporator.

Low-Pressure Cutoff or Discharge Pressure Switch This switch is located on the high side of the system and senses any low-pressure conditions. It is tied into the compressor clutch circuit, allowing it to immediately disengage the clutch when the pressure falls too low.

High-Pressure Cutout Switch This switch, normally located in the vicinity of the compressor or discharge (high side) muffler, is wired with the compressor clutch (in series). Designed to open (cut out) and disengage the clutch at 350 to 375 psi (2,400 to 2,600 kPa), it again closes and normally reengages the clutch when pressure returns to 250 psi (1,700 kPa) (higher if the system uses R-134a).

High-Pressure Relief Valve A high-pressure relief valve is incorporated into many air-conditioning systems. This valve may be installed on the receiver/dryer, compressor, or elsewhere in the high side of the system. It is a high-pressure protection device that opens (normally at 440 psi [3,033 kPa]) to bleed off excessive pressure that might occur in the system.

Compressor Control Valve This valve regulates the crankcase pressure in some compressors (commonly General Motors' V5 compressor). It has a pressure-sensitive bellows exposed to the suction side that acts on a ball and pin valve, which is exposed to high-side pressure. The bellows also controls a bleed port that is also exposed to the low side. The control valve is continuously modulating—changing the displacement of the compressor according to pressure or temperature.

Electronic Cycling Clutch Switch (ECCS) The ECCS prevents evaporator freeze-up by sending a signal to the engine control computer. The computer, in turn, cycles the compressor on and off by monitoring suction line temperature. If the temperature gets too low, the ECCS will open the input circuit to the computer, which causes the A/C clutch relay to open, disengaging the compressor clutch. Often this switch is the thermostatic switch at the evaporator.

Solar "Sunload" Sensor

More than half of the heat that is in a vehicle's passenger compartment comes from solar radiation. Many A/C systems have a solar sensor, also called the sunload sensor, that anticipates the amount of heat that will result from the sunlight. The solar sensor is usually located on top of the instrument

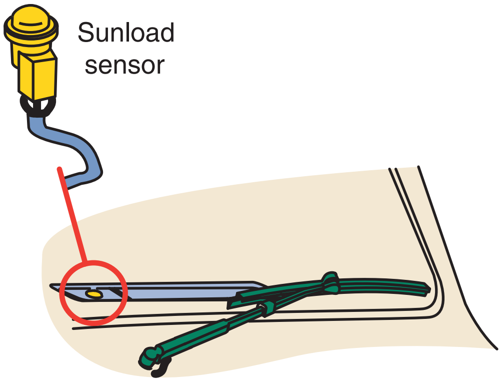

FIGURE 54–42 A solar (sunload) sensor.

panel **(Figure 54–42)**. The solar sensor is one of the main controls in many automatic climate control systems.

The solar sensor is a photo diode that receives a 5-volt reference signal from the control module. The diode normally blocks the flow of current in both directions except in the presence of light. The signal voltage from the solar sensor varies with the amount of sunlight on the sensor. When the sunlight increases, the output voltage increases, and as the sunlight decreases, the output voltage decreases. Bright sunlight causes the vehicle's interior temperature to increase; therefore, the system adds more cool air to the passenger compartment to overcome the increased heat.

Some vehicles have a solar sensor that measures sunlight at two separate angles. This allows the system to react differently on the driver and passenger sides of the vehicle. Other dual-zone systems have left and right solar sensors.

Some late-model vehicles are using infrared sensors inside the passenger compartment to measure the temperature of the passengers. Input from the sensors is used to direct airflow and control compressor operation. Other vehicles monitor which seat belts are being used so that airflow can be routed where passengers are seated to maintain a more comfortable environment for them.

Temperature Control Systems

Temperature control systems for air conditioners usually are connected with heater controls. Most heater and air-conditioning systems use the same plenum chamber for air distribution. Two types of air-conditioning controls are used: manual/semiautomatic and automatic.

Manual/Semiautomatic Temperature Controls

Air conditioner manual/semiautomatic temperature controls (MTC and SATC) operate in a manner similar to heater controls. Depending on the control setting, doors are opened and closed to direct airflow. The amount of cooling is controlled manually through the use of control settings and blower speed.

Automatic Temperature Control

An automatic or electronic temperature control system **(Figure 54–43)** maintains a specific temperature automatically inside the passenger compartment. To maintain a selected temperature, heat sensors send signals to a computer unit that controls compressor, heater valve, blower, and plenum door operation. A typical electronic control system might contain a coolant temperature sensor, in-car temperature sensor **(Figure 54–44)**, outside temperature sensor, high-side temperature switch, low-side temperature switch, low-pressure switch, vehicle speed sensor, throttle position sensor, sunload sensor, and power-steering cutout switch. Late-model vehicles are also incorporating GPS data and occupant detection via seat belt use and infrared sensors to determine where to direct airflow.

The control panel is found in the instrument panel at a convenient location for both driver and front-seat passenger access. Three types of control panels may be found: manual, push-button, or touch pad. All serve the same purpose. They provide operator input control for the air-conditioning and heating system. Some control panels have features that

FIGURE 54–43 Typical automatic climate control panel and selectors.

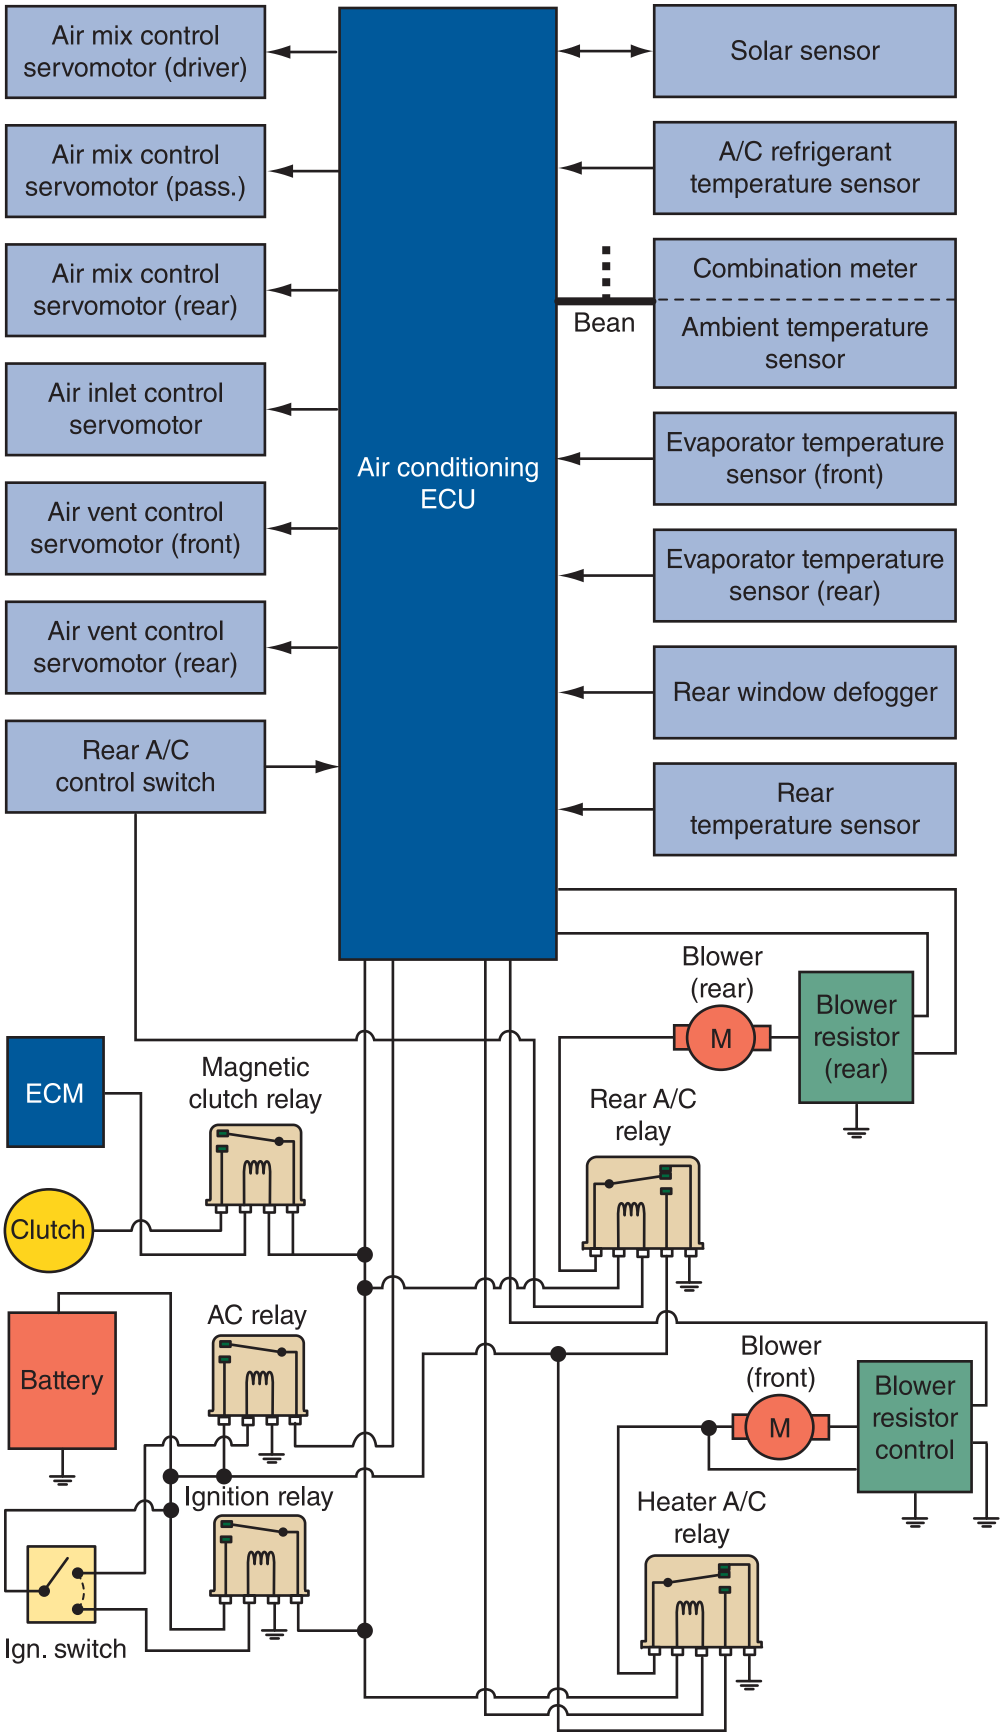

FIGURE 54-44 The layout of a computer-controlled automatic climate control system.

other panels do not have, such as provisions to display in-car and outside air temperature in degrees.

Provisions are made on the control panel for operator selection of an in-car temperature between 65 and 85 °F (18 and 29 °C) in one-degree increments. Some have an override feature that provides for a setting of either 60 or 90 °F (15 or 32 °C). Either of these two settings overrides all in-car temperature control circuits to provide maximum cooling or heating conditions.

Usually, a microprocessor is located in the control head to input data to the programmer, based on operator-selected conditions. When the ignition switch is turned off, a memory circuit remembers the previous setting. These conditions are restored the next time the ignition switch is turned on. If the battery is disconnected, however, the memory circuit is cleared and must be reprogrammed. Some vehicles are using smart-keys and individual personality settings for each key to pre-program the climate control system before the driver even enters the vehicle.

Many automotive electronic temperature control systems have self-diagnostic test provisions in which an on-board microprocessor-controlled subsystem displays a code. This code (number, letter, or alphanumeric) is displayed to tell the technician the cause of the malfunction. Some systems also display a code to indicate which computer detected the malfunction. Manufacturers' specifications must be followed to identify the malfunction display codes, because they differ from car to car.

Most late-model vehicles include the climate control part of the body control system **(Figure 54–45)**. This means that in addition to DTCs, scan data can be observed to help determine the cause of a complaint. Using the scan tool can allow you to determine if the systems inputs are being received and the information acted upon. In addition, the scan tool may have the ability to actively command the components of the system **(Figure 54–46)**. This can be very useful when testing stepper motors, blower motors, and the air-conditioning compressor clutch.

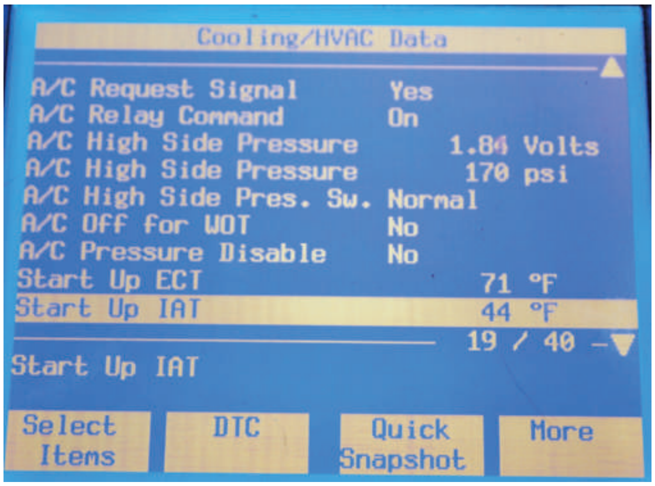

FIGURE 54–45 Using a scan tool to examine climate control data.

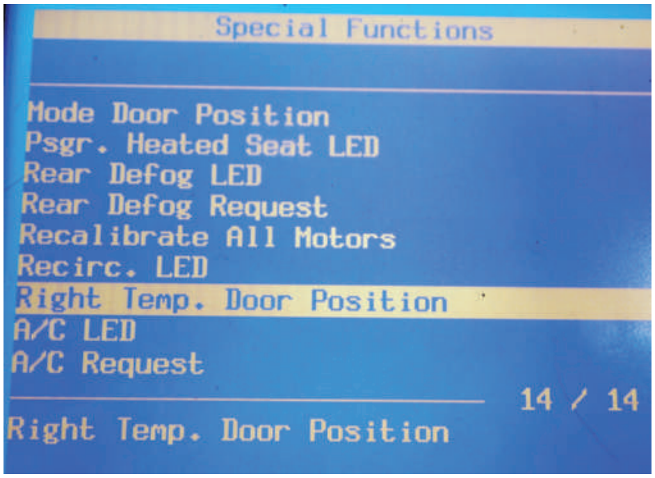

FIGURE 54–46 An example of active commands for a climate control system.

Case and Duct Systems

A typical automotive heater/air conditioner/case and duct system is shown in **Figure 54–47**. The purpose of the system is twofold: It is used to house the heater core and the air conditioner evaporator and to direct the selected supply air through these components into the passenger compartment of the vehicle. The supply air selected can be either fresh (outside) or recirculated air, depending on the system mode. After the air is heated or cooled, it is delivered to the floor outlet, dash panel outlets, or the defrost outlets.

In domestic vehicles, there are two basic duct systems employed. In the stacked-core-reheat system the basic control is in the water valve. For maximum air, the water valve is completely closed. All air enters the vehicle compartment through the heater core.

The access door, which is activated by a cable, controls only fresh or recirculated air. Recirculated air is used during maximum cold operation. The air-conditioning unit is not operative and the evaporator will not be cold. The evaporator is used only in the max air or maximum cold position. As the control level inside the car is moved, it controls the water valve by means of a vacuum or a cable to control the amount of hot water entering the heater core and the temperature of the air at the unit outlet.

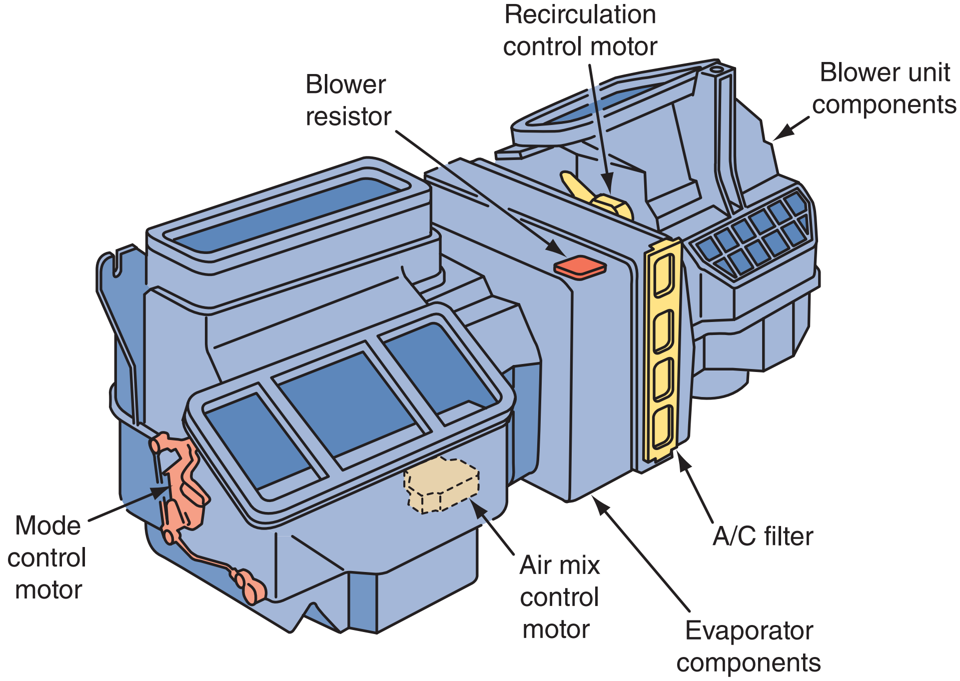

FIGURE 54–47 Typical heater/air conditioner ducts.

A blend-air-reheat mode door is found on General Motors and Ford vehicles and some truck units with factory-controlled heater system units. During heater-only operation, the air-conditioning unit is shut off, and the evaporator performs no function in air distribution or temperature control. During maximum air or extreme cold air, the air-conditioning system operates, the evaporator is cold, and the blend-air-door damper is completely closed. Only cold air enters the car.

As the control lever is moved in the vehicle from max air toward heat with the air conditioner on, the blend-air-door is moving. In maximum cold, it is completely shut. On maximum hot, it is completely open. The water valve on this unit is a vacuum on/off unit to regulate water flow. Normal position would be open. This type of blend-air system is extremely popular and can be used with or without a water valve.

To check the proper functioning of the ductwork, move the temperature control lever to see if any change occurs. If it does not, shut off the air conditioner and turn on the heater. Move the temperature control arm again to see if any change occurs. If not, check the cable and the flap door connected to the temperature control lever. You might be able to reach under the dash to reconnect the cable or free a stuck flap.

If no substantial airflow is coming out of the registers, check the fuses in the blower circuit. Remove the fan switch and test it. Check the blower motor by hot-wiring it directly to the battery with jumper cables.

Dual-Zone and Multiple-Zone Systems

Some climate control systems offer separate temperature settings for the driver's seat and passenger's seat **(Figure 54–48)** as well as for rear-seat passengers. On some BMW models, the temperature can even be adjusted separately for the driver's side upper and lower vents, focusing cooling on the upper body rather than the legs and feet. The temperature on each side of the vehicle is controlled by the doors in the ductwork for the heating and A/C system. Each side of the vehicle has its own air temperature actuator motor, controlling discharge air from the blower case. Each side also has an inside air temperature sensor and a solar sensor. The temperature setting for either side of the vehicle is made at

FIGURE 54–48 The control panel for a vehicle with dual zone and a rear heating and A/C system.

the control panel. If the passenger's control is turned off, the climate control system will maintain both sides of the vehicle according to the setting on the driver's side. When the passenger's control is turned on, the temperature on that side of the vehicle can be adjusted independently from the driver's setting.

On some systems, the climate control system is tied into the navigation system. In these cases, the A/C control module calculates the direction of the vehicle, the time, longitude, latitude, intensity of the sunlight, ambient temperature, and other information to determine the ideal amount of heat or cooling for each side of the vehicle. This system automatically controls the temperature in response to all of these inputs.

The automatic climate control also may be linked to the heated and ventilated seats. As the driver or passengers select their desired temperatures, the climate control system may heat, cool, or use a combination of heating and cooling based on temperature and humidity levels.

Rear Systems

Some vehicles, typically larger vans and SUVs, have a separate rear A/C system to provide comfort and temperature control for the passengers in the rear of the vehicle. These vehicles have a separate evaporator mounted in the rear of the vehicle **(Figure 54–49)**. A single conventional compressor is used to move refrigerant through the front and rear systems. There are also independent controls for the front and rear of the vehicle. Refrigerant lines connect the rear system to the compressor.

SUMMARY

- Ventilation, heating, and air conditioning provide for the comfort of the vehicle's passengers.
- The ventilation system on most vehicles is designed to supply outside air to the passenger compartment through upper or lower vents or both. Several systems are used to vent air into the passenger compartment. The most common is the flow-through system. In this arrangement, a supply of outside air, called ram air, flows into the car when it is moving.
- Automotive heating systems have been designed to work with the cooling system to maintain proper temperature inside the car. The heating system's primary job is to provide a comfortable passenger compartment temperature and to keep car windows clear of fog or frost.
- The main components of an automotive heating system are the heater control valve, the heater core, the blower motor and fan, and heater and defroster ducts.
- All air-conditioning systems are based on three fundamental laws of nature: heat flow, heat absorption, and pressure and boiling points.
- The major components of an air-conditioning system are compressor, condenser, receiver/dryer or accumulator, expansion valve or orifice tube, and evaporator.
- The compressor is the heart of an automotive air-conditioning system. It separates the high-pressure and low-pressure sides of the system. The primary purpose of the unit is to draw the low-pressure vapor from the evaporator and compress this vapor into high-temperature, high-pressure vapor. This action results in the refrigerant having a higher temperature than surrounding air, enabling the condenser to condense the vapor back to liquid.
- The secondary purpose of the compressor is to circulate or pump the refrigerant through the condenser under the different pressures required for proper operation. The compressor is located in the engine compartment.
- The condenser consists of a refrigerant coil tube mounted in a series of thin cooling fins to provide maximum heat transfer in a minimum amount of space. The condenser is normally mounted just in front of the vehicle's radiator.
- The receiver/dryer is a storage tank for the liquid refrigerant.
- The refrigerant flow to the evaporator must be controlled to obtain maximum cooling, while ensuring complete evaporation of the liquid refrigerant within the evaporator. This is accomplished by a thermostatic expansion valve or a fixed orifice tube.
- The evaporator, like the condenser, consists of a refrigerant coil mounted in a series of thin cooling fins. The evaporator is usually located beneath the dashboard or instrument panel.
- Although R-134a air conditioners operate in the same way and with the same basic components as R-12 systems, the two refrigerants are not interchangeable. Because it is less efficient than R-12, R-134a operates at higher pressures to make up for the loss of performance and requires new service techniques and system component designs. Basically, the higher system pressures of R-134a mean the system must be designed for those higher pressures.
- There are two basic types of automotive air-conditioning systems. They are classified according to the method used in obtaining temperature control and are known as cycling clutch systems or evaporator pressure control systems.
- Evaporator controls maintain a backpressure in the evaporator. Because of the refrigerant temperature/pressure relationship, the effect is to regulate evaporator temperature.
- Temperature control systems for air conditioners are usually connected with heater controls. Most heater and air-conditioner systems use the same plenum chamber for air distribution.
- Two types of air conditioner controls are used: manual/semiautomatic and automatic.

CHAPTER 55

AIR-CONDITIONING DIAGNOSIS AND SERVICE

OBJECTIVES

- Understand the special handling procedures for automotive refrigerants.
- Describe how to connect a manifold gauge set and a recovery/recycling machine to a system.
- Describe methods used to check refrigerant leaks.
- Determine refrigerant type, test refrigerant type and check for sealants.
- Use approved methods and equipment to discharge, reclaim/recycle, evacuate, and recharge an automotive A/C system.
- Perform a performance test on an A/C system.
- Interpret pressure readings as an aid to diagnose A/C problems.
- Diagnose and repair A/C control systems.

Air-conditioning (A/C) service, in many ways, is different from service to other parts of the vehicle. Although there are few parts in the system **(Figure 55–1)**, each component has a specific purpose and service procedure. That by itself is not a big deal. The challenge with the A/C is how it operates. The system operates on changes of refrigerant pressure. There are many things that can cause the pressure to change; some are part of the system, some are part of the environment, and some of them are faults or bad components in the system.

Service Precautions

A/C systems are extremely sensitive to moisture and dirt. Therefore, clean working conditions are very important. The smallest particle of foreign matter in an A/C system contaminates the refrigerant, causing rust, ice, or damage to the compressor. For this reason, all replacement parts are sold in vacuum-sealed containers and should not be opened until they are ready to be

installed in the system. If, for any reason, a part has been removed from its container for any length of time, the part must be completely flushed using only the recommended solvent to remove any dirt or moisture that might have accumulated during storage. If the system has been open for more than 2 minutes, the entire system must be completely evacuated and a new accumulator or desiccant bag must be installed.

Whenever it is necessary to disconnect a refrigerant line, wipe away any dirt or oil at and near the connection to eliminate the possibility of dirt entering the system. Both sides of the connection should be immediately capped or plugged to prevent the entrance of dirt, foreign material, and moisture. It must be remembered that all air contains moisture. Air that enters any part of the system carries moisture with it.

Keep all tools clean and dry. This includes the gauge set and replacement parts. Be careful not to overtighten any connection. Overtightening can result in distortion and a system leak.

When adding oil, the container and the transfer tube through which the oil will flow should be exceptionally clean and dry. Refrigerant oil quickly absorbs any moisture it contacts. For this reason, the oil container should not be opened until it is time to use it and should be capped immediately after use.

When it is necessary to open a system, have everything needed immediately available so as little time as possible is required to perform the operation. Do not leave the system open any longer than necessary.

Any time the system has been opened for repairs, it must be properly evacuated after the repair. Also, before disconnecting or removing any part, the refrigerant needs to be recovered and not allowed to escape the atmosphere.

SHOP TALK

It is important to remember that just one drop of water added to the refrigerant will start chemical changes that can result in corrosion and eventual breakdown of the chemicals in the system. The smallest amount of moist air in the refrigerant system might start reactions that can cause malfunctions.

Refrigerant Safety Precautions

- Always work in a well-ventilated and clean area. Refrigerants are colorless and invisible. Refrigerant is heavier than oxygen and will displace it in a confined area. Avoid breathing the refrigerant vapors. Exposure to refrigerant may irritate your eyes, nose, and throat.
- Refrigerant evaporates quickly when it is exposed to the atmosphere. It will freeze anything it contacts. If liquid refrigerant gets in your eyes or on your skin, it can cause frostbite. Never rub your eyes or skin if refrigerant has contacted these areas. Immediately flush the exposed areas with cool water for 15 minutes and seek medical help. Also check the SDS for the refrigerant to identify other safety-related procedures.
- An A/C system's high pressure can cause severe injury to your eyes and/or skin if a hose were to burst. Always wear eye protection when working around the A/C system and refrigerant. It is also advisable to wear protective gloves and clothing.
- Never use R-134a in combination with compressed air for leak testing. Pressurized R-134a in the presence of oxygen may form a combustible mixture. Never introduce compressed air into R-134a containers (empty or full ones), A/C systems, or A/C service equipment.
- Be careful when handling refrigerant containers. Never drop, strike, puncture, or burn the containers. Always use DOT-approved refrigerant containers.
- Never expose A/C system components to high temperatures. Heat will cause the refrigerant's pressure to increase. Never expose refrigerant to an open flame.

- Never overfill refrigerant containers. The filling level of the container should never exceed 60 percent of the container's gross weight rating. Always store refrigerant containers in temperatures below 125 °F (52 °C) and keep them out of direct sunlight.
- Refrigerant comes in 30- and 50-pound cylinders. Keep the drums in an upright position. Make sure that valves are protected by safety caps when the drums are not in use. Avoid dropping the drums. Handle them carefully.
- R-1234yf is stored and sold in white containers with red labeling or handles, whereas R-134a should be stored in light blue containers **(Figure 55–2)**. R-1234yf and R-134a should never be mixed. If the two refrigerants are mixed, contamination will occur and may result in A/C system failure. Separate service equipment must be used for the different refrigerants.
- To prevent cross-contamination, identify whether the A/C system being worked on uses R-1234yf or R-134a. Check the fittings in the system; all R-134a-based systems use ½-inch 16 ACME threaded fittings and quick-disconnect service couplings. R-1234yf systems can be identified by underhood labels clearly stating that R-1234yf is used **(Figure 55–3)**. Most manufacturers identify the type of refrigerant used by labeling the compressor. Also look for a label with the words, "CAUTION—SYSTEM TO BE SERVICED BY QUALIFIED PERSONNEL." This label or plate can be found under the hood near a component

FIGURE 55–2 R-12 should be stored and sold in white containers, whereas R-134a should be stored in light blue containers.

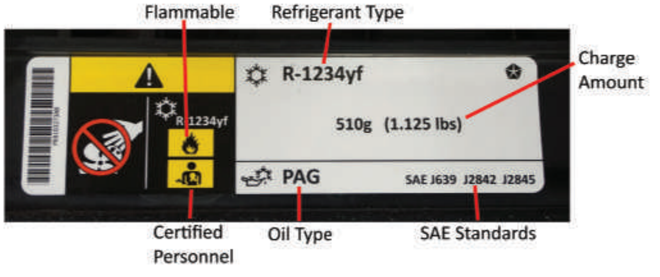

FIGURE 55–3 An underhood R-1234yf warning decal and what each item indicates.

of the system. This label also indicates what kind of refrigerant is used, the quantity required to fill the system, and the type of refrigerant oil.

- Before storing refrigerant in a tank, evacuate the tank before filling it. Tank pressure should never exceed the maximum allowable pressure as indicated on the tank.

Special Precautions for Hybrid Vehicles

Hybrid vehicles have high-voltage systems. Most often, the A/C compressor is powered by high voltage. Careless handling of some components can lead to serious injury, including death. Always follow and adhere to the precautions given by the manufacturer. These precautions are clearly labeled in their service information. All service procedures should be followed exactly as defined by the manufacturer. Being careless and/or not following the procedures can cause serious injury and can cause the battery to explode! Following is a list of commonsense items to consider when working on a hybrid vehicle:

- Because the A/C compressors are also electrically driven, special nonconducting refrigerant oils are used in HEV and EV systems **(Figure 55–4)**. Before attempting to service the A/C system, any gauge set or charging station that has been used with standard PAG oils must be purged and freed of any traces of PAG oil. Accidental contamination of the hybrid A/C system can cause electrical conduction within the compressor and potentially cause severe damage to the entire high-voltage system. Some shops keep separate equipment for working on hybrids to avoid contamination.
- Before doing any service on a hybrid vehicle, refer to the service information for that specific vehicle. All hybrids A/C systems operate in much the same way but have different systems and

FIGURE 55-4 Pay attention to all warning and service decals.

components; this is true for vehicles made by the same manufacturer.

- All high-voltage wires and harnesses are wrapped in yellow- or orange-colored insulation. Respect the color and stay away from it unless the system is depowered.
- Warning and/or caution labels are attached to all high-voltage parts. Be careful not to touch these cables and parts without the correct protective gear, such as safety gloves.
- Make sure that the high-voltage system is shut down and isolated from the vehicle before working near or with any high-voltage component.
- When working on or near the high-voltage system, even when it is depowered, always use insulated tools.
- Never leave tools or loose parts under the hood or close to the battery pack. These can easily cause a short.
- Never wear anything metallic, such as rings, necklaces, watches, and earrings, when working on a hybrid vehicle.

GO TO Chapter 35 for details on isolating the high-voltage system in a hybrid vehicle.

GO TO Chapter 6 for a complete description of the various tools used to diagnose and service A/C systems.

Warning! Under no circumstances, because of environmental and health concerns, should refrigerants or refrigerant oils be mixed. Never add one type of refrigerant to a system that has or has had another type refrigerant in it. Also make sure that the vehicle is clearly labeled as to the type of refrigerant it was converted to use.

SHOP TALK Under Section 609 of the Clean Air Act, you must be certified by an EPA-approved program to service and repair mobile air conditioning systems and buy bulk refrigerant. To become certified, a technician must have and use approved refrigerant recycling equipment and pass an exam on refrigerant recovery and recycling. A common test for this certification is administered by the ASE, MACS worldwide training/testing; some states also offer the test.

Initial System Checks

The first step in A/C diagnosis, as in all automotive diagnostic work, is to get the customer's story. Is the problem no cold air, the air from the ducts never gets cold enough, or the unit only cools at certain times of the day? The complaint could also be that the system does not work at all, or that the air blows out of the wrong ducts. An accurate description of the customer's problem helps pinpoint whether the problem is refrigerant, mechanical, vacuum, or electrical related. It also reduces diagnosis time and, most important, satisfies the customer.

Because of the many construction and operational variations that exist, there is no uniform or standard diagnostic procedure applicable to all automotive A/C systems except the performance test. For complete specific diagnostic information on a given air conditioner, check the manufacturer's service information.

A quick verification of the customer's concern can be done by starting the engine and allowing it to warm up. Move the temperature control to its full heat position. Check the amount of airflow and heat in each of the fan positions. The amount of air coming out the system should change with a change in blower speed. Also pay attention to all smells and noises. Turn the temperature control to the defrost mode. Make sure there is adequate airflow coming out of the defroster vents. Now turn the temperature control to cool or to the A/C position. Pay attention to how the engine reacts when the A/C compressor clutch engages. Also pay attention to any abnormal noises or smells. The air leaving the vents should be cool. While doing these checks, attempt to duplicate the customer's concerns and the conditions that exist when the problem occurs. If the system does not respond as expected, the system should be inspected and performance tested.

Inspection

A visual check of the A/C and cooling systems can result in an immediate diagnosis. Begin by checking the condition of the compressor's drive belt. Check the tension of the belt with a belt tension gauge (if the compressor is driven by a serpentine belt, check the belt tensioner markings). Carefully look at the compressor clutch for signs of oil leakage and belt slippage. Belt slippage may be evident by large amounts of black dust around the clutch plate. The presence of oil on or around the clutch normally indicates a bad compressor seal.

When the system is low on refrigerant charge, the performance of the system suffers. Low charge is typically the result of system leaks. The area of leakage can often be identified with a thorough inspection. Because refrigerant oil leaks out with the refrigerant, there will be an oily film at the point of leakage **(Figure 55–5)**. This film will collect dirt, and a buildup of dirt around a fitting is a good indication of a leak. Check the following refrigerant hoses and fittings for signs of leakage or damage and bends or distortion:

- Compressor to the condenser
- Condenser to the evaporator
- Evaporator to the compressor

While leaks from the metal lines are not very common, leaks from the rubber hoses and from around connections and fittings are. Make sure to check around electrical switches and any place a hose or line is secured or can contact another component.

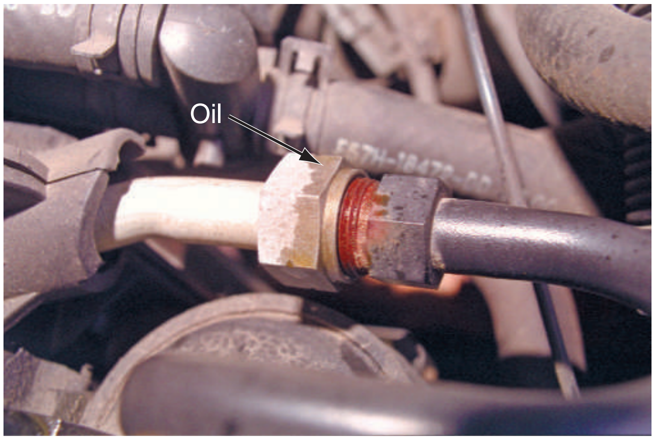

FIGURE 55–5 The oily film by this fitting is evidence of a refrigerant leak.

Visually check the condenser and the area between the condenser and radiator for a buildup of dirt, leaves, and other debris **(Figure 55–6)**. Also check the fins of the condenser for damage. If the airflow through the condenser is blocked, clean the condenser and the area around it. If the fins are damaged, they may be able to be straightened. In most cases, a damaged condenser is replaced.

A/C systems rely on many switches; these can be the cause of several operating problems. Look at the wiring and connectors to all sensors and switches carefully. Make sure all connections are secure and clean. Sometimes a bad connection or corrosion can cause intermittent problems.

In a well-ventilated area, start the engine, place the transmission in park (if the vehicle has a manual transmission, put it in neutral), set the parking brake, and turn on the A/C system to MAX cooling. On most vehicles, the electric engine cooling fan will turn on when the A/C system is turned on. Check to see if the fan(s) came on.

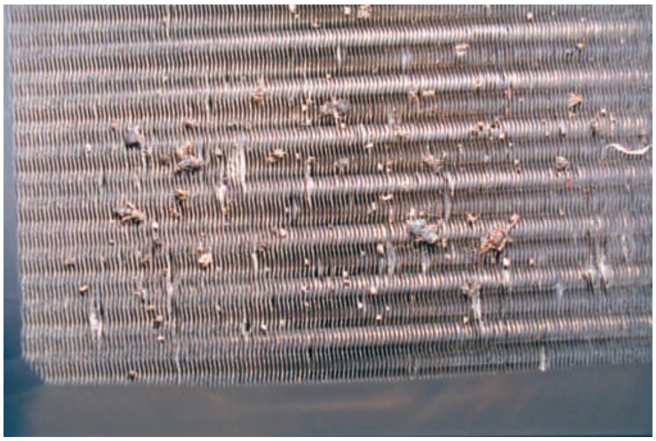

FIGURE 55–6 The condenser should be checked for damage and a buildup of debris that could cause a restriction to airflow.

Listen to the system and record any unusual sounds. Be sure to listen to the system while the compressor clutch cycles on and off. You should hear a click or a slight change in engine speed when the clutch engages. Of course, if the compressor runs at all times, the clutch will not engage or disengage with a change of the A/C controls.

Simple Checks Feel the air coming out of the vents. Cold or slightly cool air means the system has some cooling ability and the compressor is working. If the air is not cool, this means the compressor is not working or the system is not capable of providing conditioned air. If the air is warm or hot, there is probably a problem with the air duct system or the controls.

Move the temperature control from hot to cool. Feel the air from the vents. If the air temperature does not change or changes little, there is a problem with the blend door or doors in the air distribution case.

Operate the blower control through all of its speed positions; the amount of air should change. If not, there is a problem with the switch or the resistor block for the blower.

Carefully feel the discharge line from the compressor to the condenser. The line should be hot and the temperature should be the same along its full length. Any change is a sign of restriction, and the line should be flushed or replaced. Check the condenser by feeling up and down the face or along the return bends. There should be a gradual change from hot to warm as you move from the top to the bottom. Any abrupt change indicates a restriction, and the condenser has to be flushed or replaced.

If the system has a receiver/dryer, check the inlet and outlet lines. They should have the same temperature. Any temperature difference or frost on the lines or receiver tank are signs of a restriction. The receiver/dryer must be replaced. Also feel the liquid line from the receiver/dryer to the expansion valve. The entire length of the line should be warm. Typically the formation of frost on the outside of a line or component means there is a restriction to refrigerant flow. A restriction can cause the refrigerant to stay longer in the condenser. This is called condenser flooding and will cause a starved evaporator.

The expansion valve should be free of frost, and there should be a sharp temperature difference between its inlet and outlet. On vehicles equipped with the orifice tube, feel the liquid line from the condenser outlet to the evaporator inlet. A restriction is indicated by any temperature change in the liquid line before the orifice tube. Flush the line or replace the orifice tube if restricted.

FIGURE 55–7 Feeling the temperature of the pressure lines in an A/C system is part of a basic visual inspection of the system.

Carefully place your hand on the inlet line of the evaporator **(Figure 55–7)**. Do the same on the outlet. Both tubes should be colder than ambient temperature and both should be about the same temperature. If the inlet is significantly colder than the outlet, the system is probably low on refrigerant. If both lines are not colder than ambient temperature, the system needs further diagnosis.

The suction line to the compressor should be cool to the touch from the evaporator to the compressor. If it is covered with thick frost, this might indicate that the expansion valve is flooding the evaporator. The accumulator should also be cool to the touch.

Trouble Codes

Many late-model A/C systems have a self-diagnostic capability. An indicator lamp on the control panel may be used to flash codes. On most modern vehicles, part of the A/C system can be checked with a scan tool connected to the vehicle's BCM; this is especially true for those vehicles with automatic climate control. Normally the buttons on the control panel must be depressed in a certain sequence to activate the self-test.

Diagnosis

Often diagnosis of an A/C system can be done by observing the operation of the system, including listening for noises. When abnormal noises are heard, they can lead to the problem area.

PROCEDURE

To access DTCs from a system, follow these steps:

Using a Scan Tool

STEP 1 Using the service information, determine if and how to retrieve diagnostic information from the body control module (BCM).

STEP 2 Connect the scan tool.

STEP 3 Turn the ignition on.

STEP 4 Program the scan tool for that vehicle.

STEP 5 From the menu on the scan tool, select the BCM.

STEP 6 Retrieve and record all DTCs.

STEP 7 To observe the activity of the inputs and outputs, select DATA. Pay attention to any data that is outside its normal operating range, such as the ambient temperature, evaporator temperature, and low- and high-side pressures.

STEP 8 Diagnose any abnormal operating perimeters.

STEP 9 Turn the ignition off.

STEP 10 Disconnect the scan tool.

Noise

Often a customer's concern is the noise emitted by the A/C system. The following discussion covers the common abnormal noises and their causes.

Clutch Noises The clutch normally makes a clicking noise when it engages and disengages. This noise will become louder as the clutch wears. Once the clutch is severely worn, it will make a squealing noise when it is engaged. This noise can also result from oil on the clutch. A very loud screech or squeal can indicate a seized compressor. A bent drive pulley also can cause a growling or rubbing noise.

Hose Noise The change in pressures in the suction/discharge hoses can set up vibrations that cause sounds to appear from the inside of the vehicle. The noise is typically caused by a hose contacting another hose or part in the engine. Check the routing of the hoses to make sure they are not in contact. Also look for abrasions on the hoses. These can be caused by the contact.

Compressor Noise If the mounts for the compressor are loose or damaged, there will be a rattling or groaning noise. The noise is normally random. At times, loose mounts will also cause premature wear of the drive belt. Worn bearings and/or internal damage to the compressor can cause whining and growling noises when the compressor is engaged.

Hissing or Whistling This is a common and normal noise. When the A/C is turned off, a high-pitched whistle may be heard. This sound is caused by the pressures that are equalizing in the system. The high pressure moves to the low-pressure side through the metering device. This movement can result in a whistle or hiss.

Odors

A somewhat common concern of customers is a smell emitting from the A/C system. This moldy and musty smell is due to a buildup of moisture on the evaporator or the cabin filter. Moisture buildup is caused by the evaporator doing its job. As the temperature inside the vehicle is lowered, moisture is separated from the air; the moisture should be able to drain but sometimes the drain is plugged or dislocated. When a customer complains about the smell, check the evaporator drain. Also, the cabin air filter needs to be periodically changed; if it has not been changed, there will be odors that offend the passengers. Products are available to disinfect the evaporator and ductwork. These kill any odor-causing bacteria. Application of these products may require access to the evaporator, requiring disassembly of the HVAC system.

Cabin Filters Cabin air filters are designed to capture soot, dirt, pollen, and other pollutants that enter a vehicle through its heating, A/C, and defrost systems. Today more than 80 percent of all new vehicles sold in the United States have a cabin air

filter or a slot where one can be installed. Cabin air filters are typically located behind the glove compartment, under the dash, and under the hood **(Figure 55–8)**. Some cars have the filter in the HVAC case between the blower motor and evaporator core. A cabin filter is a critical part of the HVAC system. If the filter becomes dirty or clogged, less air will be able to pass through the filter. This will adversely affect the operation of the HVAC system.

Many Toyotas have an ion generator called the Plasmacluster generator **(Figure 55–9)** that improves interior air quality. It uses a high-voltage device that emits a slight sound. With these systems, dust will accumulate at the driver-side air vent. Clean it with a cloth; never spray solvent into the air vent.

FIGURE 55–8 A typical cabin air filter and housing.

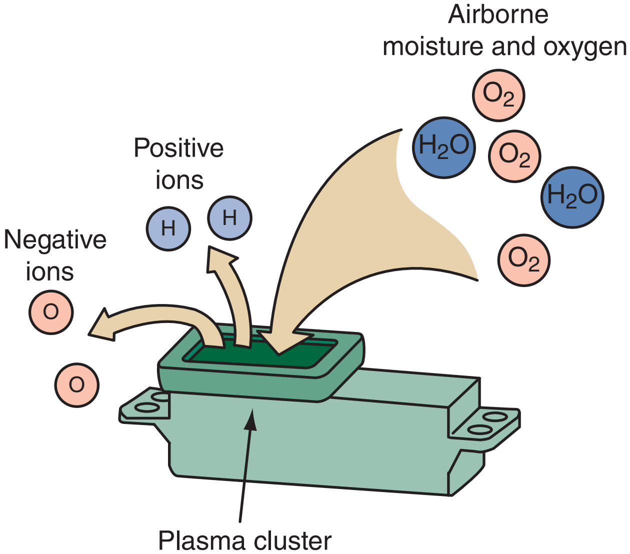

FIGURE 55–9 Many Toyotas have an ion generator called the Plasmacluster generator that improves interior air quality.

Replacement of the filters is part of a vehicle's PM program; normally a filter should be replaced every 12,000 to 15,000 miles (19,300 to 24,140 km) or at least once a year. This interval really depends on where the vehicle is typically driven. The procedure for replacing the filters varies with make and model; always check with the manufacturer.

There are two basic types of cabin air filters: particle-trapping and one that has an additional charcoal layer for odor absorption. Some particulate filters have a section that traps larger particles and another that is electrostatically charged to attract and hold smaller particles.

A charcoal type will hold a lot of odorant, and under some conditions it may release trapped odors. This is why these filters should be replaced on a regular basis. There are two alternatives to the charcoal filter: a filter element impregnated with baking soda and a filter with a biocidal cartridge. Both prevent the growth of bacteria, mold, mildew, algae, and yeast.

Some vehicles are also equipped with an air quality sensor in the main inlet duct of the HVAC system or in front of the condenser. The sensor detects the presence of undesirable gases in the incoming air, specifically carbon monoxide and nitrogen dioxide. Within seconds of detection, the ventilation system closes the outside air inlet and recirculates the air until the pollutants are no longer at an unacceptable level.

Performance Testing

Performance testing provides a measure of A/C system operating efficiency. A manifold pressure gauge set is used to determine both high and low pressures in the refrigeration system. The desired pressure readings will vary according to temperature. Use temperature/pressure charts as a guide to determine the proper pressures. At the same time, a thermometer is used to determine air discharge temperature in the passenger compartment **(Figure 55–10)**.

Service Valves and Quick-Connect Fittings

System service valves provide the attachment point for the manifold pressure gauge set. They are located in the low and high sides of most A/C systems. Both

FIGURE 55–10 A thermometer is used to determine air discharge temperature in the passenger compartment.

R-134a **(Figure 55–11A)** and R-1234yf systems have quick-connect fittings though each is different and not interchangeable **(Figure 55–11B)**. The service valve caps on R-1234yf systems are also tethered to the line to help prevent losing the caps when removed. Both systems use two different sized quick-connect fittings; the low-pressure fitting being the smaller of the two. This prevents incorrect connection of the service hoses. The service hose fittings should have a manual valve that threads through the fitting and down to open the service port connection. Once finished, loosening the valve retracts the pin and allows the system to seal before removing the fittings. This is to reduce the amount of refrigerant released when the service hoses are disconnected from the system.

Stem Valves The stem valve was sometimes used on older two-cylinder reciprocating-piston compressors. The service valves are mounted on the compressor head. These valves can be used to isolate the rest of the A/C system from the compressor when the compressor is being serviced. These valves have a stem under a cap with the hose connection directly opposite it.

Purity Test

When you are not sure of the refrigerant used in a system or if you suspect that a mixing of refrigerants has occurred, you should run a purity test and/or use a refrigerant identifier **(Figure 55–12)**. In addition

> **Caution!** Always wear safety goggles when working on or around A/C systems.

to determine what is in the system, identification is also important because several refrigerants that are on the market are flammable. Knowing what refrigerant is in the system, or what condition it is in, will help you protect your equipment from damage and

FIGURE 55–12 A refrigerant identifier.

determine what steps you need to take to properly service the system.

It is recommended that the system be tested for sealant identification and/or contamination before conducting the purity test. Many of the A/C recharge products available over the counter contain some type of sealant. Reclaiming the refrigerant and sealant can cause damage to your equipment. It is recommended that shops have sealant ID kits **(Figure 55–13A)** and special filters installed on their charging stations to help prevent contamination. A small sample of refrigerant is drawn into the test kit; this acts like a leak in the system **(Figure 55–13B)**. If sealant is present it will react with the moisture in the air and solidify in the small disposable detection cartridge. Systems that contain sealant can still be reclaimed but special filters are used to trap the sealant, dyes, and any other contaminants that are present.

Manifold Pressure Gauge

The manifold gauge set is one of the most important A/C tools. It is used when discharging, charging, and evacuating the system; it also is used for diagnosing the system. With the new legislation on handling refrigerants, all gauge sets are required to

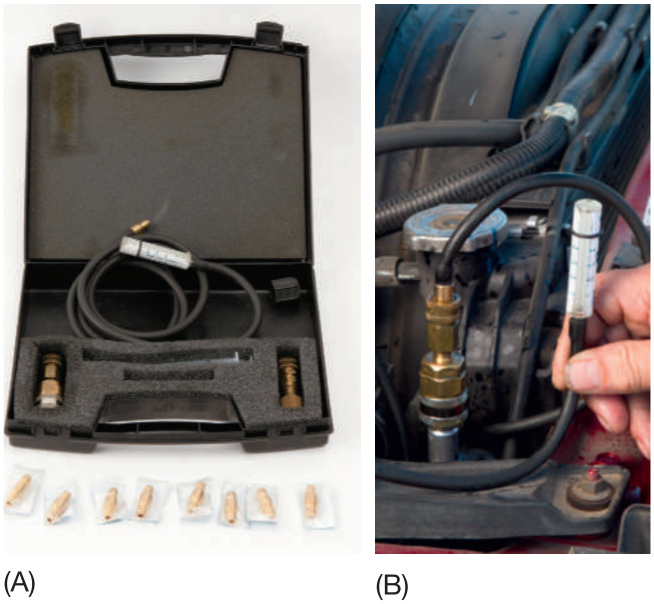

FIGURE 55–13 (A) A typical refrigerant identification kit. (B) Taking a sample of the refrigerant.

FIGURE 55–14 The test connectors with shutoff valves for an R-134a system.

have a valve device to close off the end of the hose so that the fitting not in use is automatically shut **(Figure 55–14)**.

The low-pressure gauge is graduated into pounds of pressure from 1 to 120 (with cushion to 250) in 1-pound graduations, and, in the opposite direction, in inches of vacuum from 0 to 30. This is the gauge that should always be used in checking pressure on the low-pressure side of the system. The gauge at the right is graduated from 0 to 500 pounds pressure in 10-pound graduations. This is the high-pressure gauge that is used for checking pressure on the high-pressure side of the system.

The center manifold fitting is common to both the low and the high sides and is for removing or adding refrigerant to the system. When this fitting is not being used, it should be capped. A test hose connected to the fitting directly under the low-side gauge is used to connect the low side of the test

manifold to the low side of the system. A similar connection is found on the high side.

The gauge set has hand valves that isolate the low and high sides from the central portion of the manifold. During all tests, both the low- and high-side hand valves are in the closed position (turned inward until the valve is seated).

Because R-134a is not interchangeable with R-1234yf, separate sets of hoses, gauges, and other equipment are required to service newer vehicles. Manifold gauge sets for R-134a can be identified by one or all of the following: Labeled "FOR USE WITH R-134a," labeled "HFC-134" or "R-134a," and/or have a light blue color on the face of the gauges. Also, R-134a service hoses have a black stripe along their length and are clearly labeled "SAE J2196/R-134a." The low-pressure hose is blue with a black stripe. The high-pressure hose is red with black stripe, and the center service hose is yellow with a black stripe. Service hoses for one type of refrigerant will not connect into the wrong system, because the fittings for an R-134a system are different from those used in an R-1234yf system. The operating pressures and temperatures of R-1234yf systems are similar to that of R-134a systems.

Connecting the Gauge Set Identify the type of refrigerant used in the systems and obtain the appropriate gauge set. Locate the high- and low-side service valves. Make sure the valves on the gauge set are fully closed. Remove the protective cap from the low-side service valve and connect the low-side service hose to the service valve. Then remove the protective cap from the high-side service valve and connect the high-side service hose to the valve.

FIGURE 55–15 Measure the temperature of the air entering the condenser.

Testing Procedures

PROCEDURE

To conduct a performance test, follow these steps:

STEP 1 With the manifold gauge set connected, start the engine in neutral or park with the parking brake on and allow the engine to run for about 5 minutes.

STEP 2 Increase engine speed from 1,500 to 2,000 rpm.

STEP 3 Keeping your hands away from the cooling fan, measure and record the temperature and humidity of the air in front of the condenser **(Figure 55–15)**.

STEP 4 Place a high-volume fan in front of the radiator grille to ensure an adequate supply of airflow across the condenser.

STEP 5 Adjust the A/C controls to maximum cooling and high blower position.

STEP 6 Place the thermometer in the center air duct in the dash. Measure and record the temperature.

STEP 7 Read the high and low pressures. If the vehicle uses a cycling clutch system, note the pressures at which the clutch engages and disengages.

STEP 8 Compare your readings to specifications.

STEP 9 Return the engine to a normal idle speed.

STEP 10 Close the service hose valves, if so equipped.

STEP 11 Disconnect the service hoses.

STEP 12 After disconnecting the gauge lines, check the valve areas to be sure that the service valves are correctly seated and that the Schrader valves are not leaking.

STEP 13 Reinstall the protective caps on the service valves.

STEP 14 Turn off the A/C and the engine.

Always refer to the manufacturer's pressure charts when using observed pressures for diagnostics **(Figure 55–16)**. It is normal for the gauge readings to fluctuate as the clutch cycles and the heat load

changes, but they should not greatly fluctuate. Operating pressures will vary with humidity as well as with outside air temperature. Accordingly, on more humid days, operating pressures will be on the high side of the acceptable pressure range. On less humid days, the operating pressures will read toward the lower side. If operating pressures are found to be within the normal range, the refrigeration portion of the A/C system is functioning properly. This is further confirmed with a check of evaporator outlet air temperatures.

Here are some guidelines to help you interpret abnormal readings:

- If the observed pressures are below the normal ranges, this indicates an undercharged system.
- If both pressures are above normal pressures, the system is overcharged or there is insufficient air flowing through the condenser.
- If there is normal low-side pressure but higher-than-normal high-side pressure, this indicates there is air in the system.

- If both gauges show equally low pressures but a medium amount of pressure, this indicates a fully charged system with an inoperative compressor.
- If the high-side pressure is too high, suspect air in the system, too much refrigerant in the system, a restriction in the high-side of the system, and poor airflow across the condenser.
- If the high-side pressure is too low, suspect a low refrigerant level or defective compressor.
- If the low-side pressure is higher than normal, suspect refrigerant overcharge, a defective compressor, or a faulty metering device.
- If the low-side pressure is lower than normal, suspect a faulty metering device, poor airflow across the evaporator, a restriction in the low side of the system, or a system that is undercharged with refrigerant.

Evaporator Outlet Temperature Evaporator outlet air temperature also varies according to outside (ambient) air and humidity conditions. Further variations depend on whether the system is controlled by a cycling clutch compressor or an evaporator pressure control valve. Because of these variations, it is difficult to pinpoint what the evaporator outlet air temperature should be for all applications. In general, with low air temperatures and humidity, the evaporator outlet air temperature should be from 35 to 40 °F (1.7 to 4.4 °C). On the other extreme of high temperatures and humidity, the evaporator air outlet temperature might be in the 55 to 60 °F (12.8 to 15.6 °C) range.

Leak Testing

Testing the refrigerant system for leaks is one of the most important phases of troubleshooting. Over a period of time, the A/C systems may lose or leak some refrigerant. Modern systems that are in good condition should have nearly zero refrigerant loss per year. Current infrared leak detectors can find leaks as small as 0.15 oz/year or about 4 grams per year. Higher loss rates signal a need to locate and repair the leaks.

Leaks are often evident by low-pressure gauge readings. Normally, if there is some pressure in the system, the leak is a small one. Large leaks typically will empty the system.

Leaks are most often found at the compressor hose connections and at the various fittings and joints in the system. Refrigerant can be lost through hose permeation. Leaks can also be traced to pinholes in the evaporator caused by acid, which forms when water and refrigerant mix. Because oil and refrigerant leak out together, oily spots on hoses, fittings, and components mean there is a leak.

When the source of leakage is not obvious, a leak detector can be used to locate it. However, to use a leak detector, there must be some refrigerant in the system. Most manufacturers say that a leak detector will only work if the high-side pressure is above 60 psig. If the pressure is below this, add no more than 1 pound (453.6 grams) of refrigerant to the system and then check for leaks.

Be sure to check the entire system, including inside the passenger compartment around the evaporator. If a leak is found at a connection, tighten the connection carefully and recheck. If the leak is still apparent, the affected components should be replaced. After leak testing, and before opening the system for repairs, use the recovery station to remove all refrigerant from the system.

Stop Leak Products Products that can be added to seal leaks in the system are sold. Many OEMs do not recommend their use. Sealants may cause buildups in the system, causing unwanted restrictions. They may also cause compressor clutch problems if there is a leak around the compressor shaft. These manufacturers also will void the warranty on the system if a sealant has been installed. Always check with the manufacturer before adding a sealant to the system.

Electronic Leak Detector

This is the preferred method of leak detection; it is safe, effective, and can be used with all types of refrigerants. The hand-held battery-operated electronic leak detector **(Figure 55–17)** contains a test probe that is moved under the areas of suspected leaks. (Remember that refrigerant gas is heavier than air, so

FIGURE 55–17 An electronic leak detector.

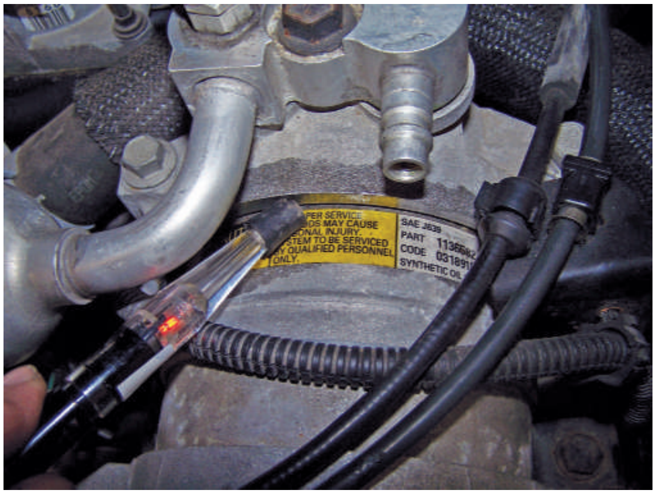

FIGURE 55–18 When the probe of the leak detector is near the area of a leak, its light will flash.

the probe should be positioned below the test point.) An alarm or a buzzer on the detector indicates the presence of a leak **(Figure 55–18)**. On some models, a light flashes to establish the leak.

Electronic (halogen) leak detectors are common because of their accuracy and ability to detect several types of refrigerants. This type of detector must be capable of measuring a leak as small as 0.15 ounces or 4 grams per year. When selecting a leak detector, make sure the unit meets the SAE J2791 performance standard for refrigerant leak detection. J2791 sets standards for leak detection capabilities as well as how quickly and from what distance the leak can be found.

When using an electronic leak detector, keep the following in mind:

- Many leak detectors have the sensing unit inside the tool and not at the tip.
- When checking the system, move slowly, about an inch per second, to allow the detector to get a sample of the air.
- Normally, small leaks can only be found when the A/C and engine are turned off and there are no cooling fans operating.
- Low-side leaks may be easier to find when the system is turned off.
- High-side leaks may be easier to find when the system is running.

Fluorescent Dye Leak Detection

A common method of leak detection is using a fluorescent dye. The dye can be injected into the system for testing. Many new vehicles have R-134a fluorescent dye installed in the refrigerant system when the vehicle is produced. The fluorescent dye mixes and flows with the PAG oil throughout the A/C system. In these systems, additional dye should not added unless more than 50 percent of the refrigerant oil has been lost because of bad fittings, hose rupture, or other major leakage. There is no need to add dye to the system after the system has been flushed. Part of the flushing process is the replacement of the accumulator or receiver/dryer. New accumulators or receiver/dryers for these systems have a fluorescent dye element in the desiccant bag. The element will dissolve while the system runs, adding the correct amount of dye to the system.

Fluorescent dye may need to be added to a system that was produced with dye in the system or added to other systems for leak detection. This can be done by injecting it into the system or by pouring it directly into a removed component. Normally to do this, a UV leak detection kit **(Figure 55–19)** is used to

FIGURE 55–19 The parts included with a UV leak detection tester.

find the source of any leakage. This kit includes the fluorescent dye, dye injector, high intensity UV lamp, and tinted protective safety glasses or goggles. To begin the detection process, the dye must be injected into the system. It is important to note that all fluorescent dyes are not compatible with PAG oil. Before adding dye to the system, make sure it is the right type. Make sure the right quantity of dye is installed; never overcharge the system with dye. And always follow the instructions for the detector and do not install too much dye.

There are two basic ways to inject dye into the system. One uses an A/C charging station and a manifold gauge set. This should only be used when the system is not fully charged. A small tank of dye and an injector is attached to the center hose on the gauge set. The dye is added with some refrigerant to the low side of the system.

When the system is fully charged, a special kit must be used. The kit contains a reservoir for the dye and is connected between the high-pressure and low-pressure service valves. With the A/C turned on, the high-side valve is opened and remains open until the dye has left the reservoir. This method does not add refrigerant to the system.

Run the A/C system for several minutes to distribute the dye evenly. Put on the tinted goggles and examine the system with the UV lamp. System leaks will be apparent by a luminous yellow-green **(Figure 55–20)** trace. When checking for leaks, inspect all components, lines, and fittings of the refrigerant system. This includes the evaporator and its drain tube. If a leak is found, continue checking the rest of the system because there may be more than one leak. It is important to remember that PAG oil is water soluble. Therefore, condensation on the evaporator or the refrigerant lines may wash the oil and fluorescent dye away from where the leak is.

If a leak is found, recover the refrigerant. Then correct the problem. Next, evacuate and charge the system. Thoroughly clean all traces of fluorescent dye from any area where leaks were found. Run the system for a short time and recheck the system for leaks to verify the repair.

FIGURE 55-20 When the system is checked with a UV leak detection kit, system leaks will be apparent by a luminous yellow-green trace.

Leak Detector Fluid Leaks can also be located by applying leak detector fluid around areas to be tested. Detection fluids are available for R-12 and R-134a systems; make sure you use the correct one for the refrigerant you are looking for. If a leak is present, it will form clusters of bubbles around the source **(Figure 55–21)**. A very small leak will cause white foam to form around the leak source within several seconds to a minute. Adequate lighting over the entire surface being tested is necessary for an accurate diagnosis.

SHOP TALK

Some OEMs, such as Toyota, do not recommend the use of leak-detecting dyes. Always check the manufacturer's recommendations before adding dyes to the A/C system.

properly circulate through the system before it can be useful. This can be anywhere from 15 minutes to several days, depending on the size of the leak.

Emptying the System

Before the system is opened for service, all refrigerant in the system needs to be recovered. However, prior to doing this, the refrigerant needs to be positively identified. This is necessary to prevent mixing of refrigerants. Although the system may be clearly marked as using a particular refrigerant, there are many different refrigerants available that may have been added to the system. Some of these are blends and not pure. Any refrigerant that is not pure is considered contaminated. Also, the passage of a refrigerant that the recovery machine is not designed for will contaminate the machine and the storage containers. Identifying refrigerant should also take place before using a container of recycled refrigerant just to be safe.

The composition of refrigerant is analyzed by a refrigerant identifier. This tool takes a sample of the refrigerant from the low side of the system and analyzes it. The amount of R-12 or R-134a is displayed on the tool. All refrigerants that are less than 98 percent pure will fail the tests and should not be recycled. This should be recovered into a storage container labeled as contaminated. This container should only be used for contaminated refrigerant.

There are many different identifiers available; always follow the specific instructions for the tool you will be using.

Recovery

There are currently two types of refrigerant recovery/recycling machines: the single pass and the multipass. Both have the ability to draw the refrigerant from the vehicle, filter and separate the oil from it, remove moisture and air from it, and store the refrigerant until it is reused.

In a single-pass system, the refrigerant goes through each stage before being stored. In multipass systems, the refrigerant goes through all stages of oil separation and drying before being stored. When set to recycle, the refrigerant then passes back through the dryer until all moisture is removed. Either system is acceptable if it has the UL-approved label.

Recovery of R-1234yf

With the new refrigerant also comes new regulations and service procedures. SAE Standard J2843 for flammable refrigerants requires a dedicated recovery/recycle/recharge (RRR) machine to service R-1234yf systems. The new machine standards include the following:

- Recover 95 percent of the refrigerant in the system.
- Recharge the system within ½ ounce of the specification.
- A required filter change after 150 pounds of recovered refrigerant.
- A built-in refrigerant identifier or have a USB port to connect one.
- Prevents the recovery of contaminated refrigerant (must be more than 98 percent pure).
- Will not recharge the system if there's a leak detected.
- Has ventilation fans and nonsparking motors, switches, relays, and other components that could ignite the refrigerant.

Some machines, particularly those at new car dealerships, may have specific information that needs to be input before the machine will work, such as the vehicle VIN, repair order information, and technician ID.

To minimize the amount of refrigerant released to the atmosphere when A/C systems are serviced, always follow these steps.

1. The recovery/recycling equipment **(Figure 55–22)** must have shutoff valves within 12 inches of the hoses' service ends. With the valves closed, connect the hoses to the vehicle's A/C service fittings.
2. Always follow the equipment manufacturer's procedures for use. Recover the refrigerant from the vehicle and continue the process until the vehicle's system shows vacuum instead of pressure.

FIGURE 55–22 A R-1234yf refrigerant management center that is capable of doing all necessary refrigerant services.

Turn off the recovery/recycling unit for at least 5 minutes. The unit may default to a longer time, such as 10 minutes, for leak detection. If the system still has pressure, repeat the recovery process to remove any remaining refrigerant. Continue until the A/C system holds a stable vacuum for 2 minutes.

3. Close the valves in the recovery/recycling unit's service lines and disconnect them from the system's service fittings. On recovery/recycling stations with automatic shutoff valves, make sure they work properly.
4. You may now make repairs and/or replace parts in the system.

Recycling

Recycling collects old refrigerant from the system being serviced and cleans it up and prepares it to be used in the future. If recycled refrigerant is sent to a reclamation site, the EPA requires documentation of the name and address of the facility to which the refrigerant is sent. All recycled refrigerant must be safely stored in DOT CFR Title 49 or UL-approved containers. Containers specifically made for R-134a should be so marked. Before any container of recycled refrigerant can be used, it must be checked for noncondensable gases.

The SAE has set standards for recycled R-134a and R-1234yf to make sure the refrigerants provide proper system performance and longevity. J1991 and J2099 are purity standards for recycled refrigerant and specifies a limit in parts per million (ppm) by weight. These limits are placed on three potential contaminants. There can be no more than 15 ppm of moisture in recycled R-134a and 10 ppm for new R-134a. The limit for the amount of refrigerant oil in R-134a is 500 ppm. The additional contaminant looked at by the SAE is air or noncondensable gases. There should be no more than 1.5 percent by volume in R-134a or R-1234yf.

Because the A/C service equipment may recycle in addition to recover and recharge, periodic maintenance (such as filter changes) are necessary to keep the unit operating properly. Before using the A/C equipment, you should read and understand its operation and ensure that it is in proper working condition. Refer to the manual that came with the equipment to determine what type of maintenance is required and how often.

General Service

All refrigerant must be discharged from the system before repair or replacement of any component (except for compressors with stem service valves). The refrigerant must be recovered and recycled. This means the refrigerant cannot be released into the atmosphere. According to Section 609 of the Federal Clean Air Act, no one repairing or servicing a motor vehicle's A/C system can do so without the proper refrigerant recovery recycling equipment. It further states that no one can do this service unless that person is properly trained and certified.

Before replacing any part in the system, recover the refrigerant first. When replacing a part in an A/C system make sure it is the correct replacement part. Also make sure it is properly installed and the line connections are secure. After a component has been replaced it may be necessary to add refrigerant oil to the system to replace the oil that settled in the replaced component. Typically the amount of oil can be estimated by considering the component replaced. Some parts, such as an orifice tube, require special tools for removal and installation.

Refrigerant Oil

Normally the only source of lubrication for a compressor and other moving parts in the A/C system is the oil mixed with the refrigerant. The oil required for the system depends on the refrigerant used in it and if the vehicle is a hybrid or electric vehicle.

Generally, compressor oil level is checked only where there is evidence of a major loss of system oil that could be caused by a broken refrigerant hose, severe hose fitting leak, badly leaking compressor seal, or collision damage to the system's components.

When replacing refrigerant oil, it is important to use the specific type and quantity of oil recommended by the manufacturer. If there is a surplus of oil in the system, too much will circulate with the refrigerant, causing the cooling capacity of the system to be reduced. Too little oil results in poor lubrication. When there has been excessive leakage or it is necessary to replace a part of the A/C system, certain procedures must be followed to ensure that the total oil charge in the system is correct after the repair. Most A/C recovery/recycling equipment will display how much oil has been removed with the refrigerant **(Figure 55–23)**.

When the compressor is running, oil gradually leaves the compressor and is circulated through the system with the refrigerant. Eventually a balanced condition is reached in which a certain amount of oil is retained in the compressor and a certain amount is continually circulated. If a component of the system is replaced after the system has been operated, some oil goes with it. Always add the specific amount and the correct type of oil when replacing a part **(Figure 55–24)** and do so according to the manufacturer's recommendations.

GO TO Chapter 54 for a discussion on the various oils used in A/C systems.

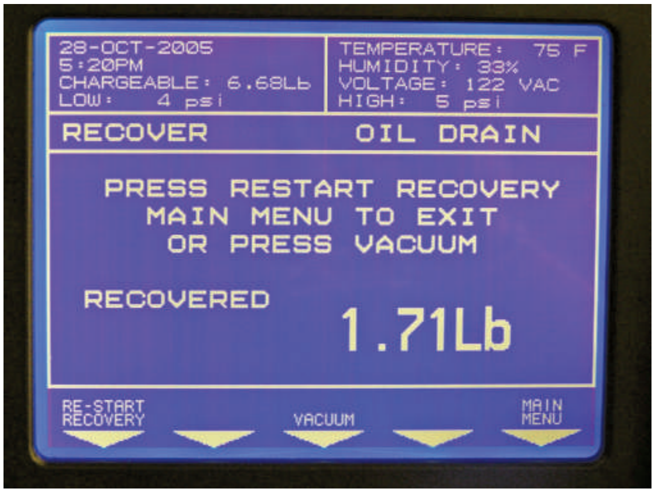

FIGURE 55–23 Most A/C recovery/recycling equipment will display how much oil has been removed with the refrigerant.

FIGURE 55–24 When a part is replaced, make sure to add the correct amount and type of refrigerant oil for that part to the system.

Clutch Service

The compressor clutch is engaged by a magnetic field and disengaged by springs when the magnetic field is broken. When the controls call for compressor operation, the electrical circuit to the clutch is completed, the magnetic clutch is energized, and the clutch engages the compressor. When the electrical circuit is opened, the clutch disengages the compressor.

The clutch assembly should be carefully inspected for discoloration, peeling, or other damage. If there is damage, replace the clutch assembly. Also check the play and drag of the compressor pulley bearing by rotating the pulley by hand. Replace the clutch assembly if it is noisy or has excessive play or drag. The field coil for the clutch can be checked with an ohmmeter **(Figure 55–25)**. The exact testing points and acceptable resistance readings are given in the vehicle's service information. If resistance is not within specifications, replace the field coil. Also, check the clutch clamping diode.

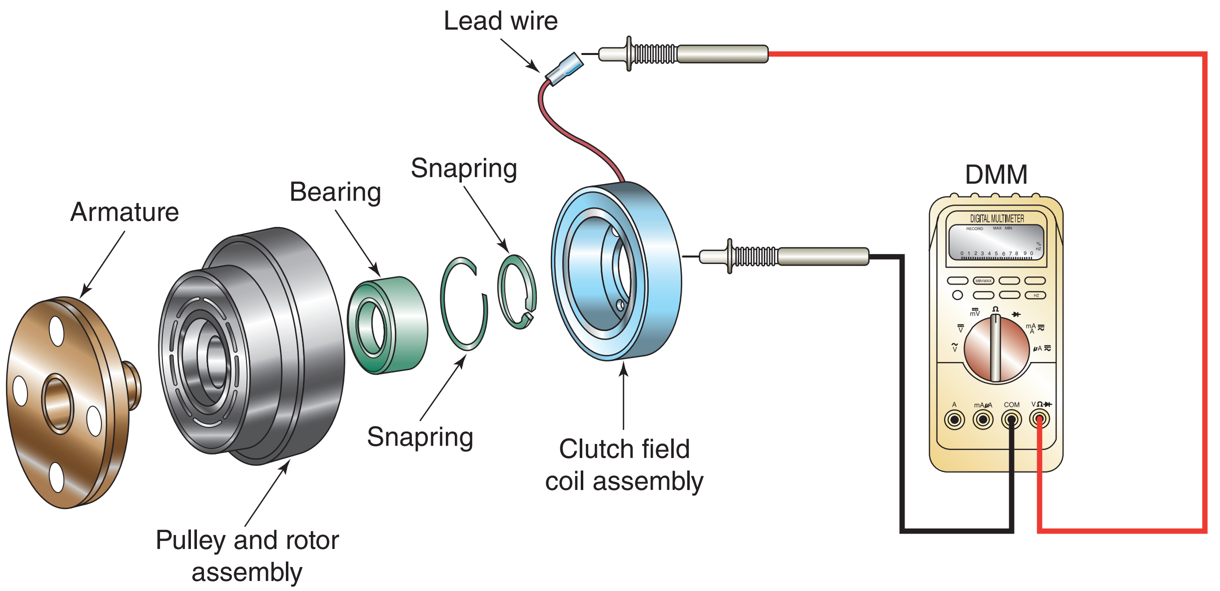

FIGURE 55–25 Testing a compressor clutch with an ohmmeter.

If the clutch is not operating, check the electrical connections to it. Make sure they are secure and corrosion free. Then, check for power to the clutch with a testlight or DMM. If there is no power, locate and repair the problem. If there is power to the clutch, check the ground circuit with a DMM. If there is power and a good ground, the clutch is defective and must be replaced.

Clutch Clearance Nearly all clutch assemblies have a clearance spec for the distance between the clutch and the pressure plate. This clearance is measured with a feeler gauge. If the clearance is too great, the clutch may slip and cause a scraping or squealing noise. If the clearance is insufficient, the compressor may run when not electrically activated and the clutch may chatter at all times. As the clutch assembly wears, the clearance increases and therefore should be checked and adjusted whenever symptoms suggest doing so. Always follow the specific procedures given by the manufacturer for measuring and correcting the gap.

Measure the clearance between the rotor pulley and the armature plate **(Figure 55–26)**. Do this at more than one location. If the clearance is not within the specified limits, remove the armature plate and add or remove shims as needed to increase or decrease the clearance. The shims are available in different thickness and it is recommended that no more three shims be installed to correct the clearance.

Some clutches are press-fit to the compressor shaft. The gap of these clutches is adjusted by tightening the retaining bolt. With a feeler gauge placed between the clutch plate and pulley, tighten the bolt until the feeler gauge of the specified size has a slight drag.

FIGURE 55–26 Check the gap between the armature plate and the pulley with a feeler gauge.

Clutch and Pulley Replacement On some vehicles, the clutch can be serviced on the vehicle. On others, the compressor assembly must be removed to service the clutch. Refer to the service information on your specific vehicle to determine what must be done.

Normally, to remove the clutch assembly, the magnetic clutch hub must be held while the retaining bolt is loosened. After the bolt is removed, the clutch hub and shims can be removed. This will give access to a snapring around the compressor shaft. Using

snapring pliers, expand and remove the snapring and then remove the rotor of the magnetic clutch. Be careful not to damage the compressor seals while doing this. Now, remove the snapring for the clutch stator and then the stator.

When installing a new clutch assembly, begin by aligning the protrusion on the stator with the notch on the compressor. Then install a new snapring with its chamfered side facing up. Install the clutch rotor with a new snapring. Now install the clutch shims and hub. Hold the hub while tightening the center bolt to specifications. While installing the clutch assembly, make sure all parts are kept clean and free of oil or grease.

Clutch Pulley Bearing Replacement The clutch pulley can be a source of unwanted noise and can be replaced on most systems. To replace the bearing, remove the pulley. Use a bearing driver or press to push the bearing out of the front of the pulley. To install a new bearing, align the pulley and press it into place.

Compressor Service

Compressors are normally replaced, rather than rebuilt, when they are faulty or damaged. The following procedure is typical for a non-electric compressor.

PROCEDURE

To remove and install a compressor, follow these steps:

STEP 1 Identify and disconnect all electrical connections to the compressor.

STEP 2 Discharge the system using a recovery/recycling machine.

STEP 3 Disconnect the refrigerant lines at the compressor. Immediately cap or seal the ends of the lines or hoses.

STEP 4 Remove the drive belt for the compressor.

STEP 5 Loosen and remove the compressor mounting brackets. Note the location of the bolts because they are typically of a different length.

STEP 6 Remove the compressor.

STEP 7 To install a compressor, reverse the removal procedure. Make sure the drive belt is tightened to the proper tension.

Shaft Seal Replacement The seal at the compressor shaft is a common source of leaks. To replace the seal, remove the clutch assembly. Then remove the internal snapring that holds the seal in place. Install the special seal remover/installer tool against the face of the seal. Twist it to expand the jaws of the tool on the seal. With a gentle twisting and pulling motion, remove the seal. Then remove and discard the O-ring seal that is located between the housing and the shaft seal.

Lubricate and install a new O-ring into its groove. Coat the new shaft seal with refrigerant oil. Then place the seal into the jaws of the seal remover/installer tool. Install a seal protector over the threads of the compressor's shaft **(Figure 55–27)**. With a gentle twisting motion, slide the seal over the protector and into the groove in the compressor. Release the installer from the seal. Then reinstall the snapring and clutch assembly. The system will need to be evacuated before it is recharged.

Flushing Compressor failure causes foreign material to pass into the system. The condenser must be flushed and the receiver/dryer or accumulator replaced. Filter screens are sometimes located in the suction side of the compressor and in the receiver/dryer. The compressor inlet screen should be replaced whenever the compressor is replaced. These screens confine foreign material to the compressor, condenser, receiver/dryer, and connecting hoses. If a screen becomes clogged, it will block the flow of refrigerant. Use only recommended flushing solvents. Never use CFCs or methylchloroform for flushing. Some manufacturers recommend replacing

FIGURE 55–27 Install the protector over the threads of the compressor shaft. Place the new seal on the installer and install the seal with a gentle twisting motion.

FIGURE 55–28 An inline filter.

the clogged components and installing a liquid line (inline) filter just ahead of the expansion valve or orifice tube instead of flushing the system. If flushing is recommended by the manufacturer, use only the recommended flushing agent and follow the specified procedures. After the system has been flushed, be sure to oil all components that require it.

Inline Filters The most effective way to collect debris that may be in the system is to install an inline filter **(Figure 55–28)**. These filters should be installed whenever the compressor seizes or has severe damage and needs to be replaced. A filter should also be installed if the expansion valve or orifice tube is plugged with debris. Filters can contain an orifice and these should be installed in a different location than filters without an orifice. If the filter does not have an orifice, it should be installed in the liquid line between the condenser outlet and the evaporator inlet. If the filter has an orifice, it is installed between the low-pressure side of the system beyond the expansion tube. If the filter has a built-in orifice, remove the original expansion tube. In either case, the filter should be inserted at a point where the refrigerant line is straight.

To install the filter, cut the line at the desired filter location. Make sure the cut is smooth and straight. Slide the ferrules, cones, and seals for the filter onto each end of the cut line. Lubricate the seals and insert the filter and tighten the ferrules. Make sure the lines are properly sealed, and then evacuate and charge the system. When finished, check the installation for leaks.

Compressor Controls

The ambient temperature sensor or the engine's IAT measures outside air temperature to prevent compressor clutch engagement when A/C is not required or when compressor operation might cause internal damage to the seals and other parts. The switch is in series with the compressor clutch electrical circuit and closes at about 37 °F (2.8 °C). At all lower temperatures, the switch is open preventing clutch engagement.

In cycling clutch systems, a thermostatic switch is placed in series with the compressor clutch circuit so it can turn the clutch on or off. It de-energizes the clutch and stops the compressor if the evaporator is at the freezing point. When the temperature of the evaporator approaches the freezing point, the thermostatic switch opens the circuit and disengages the compressor clutch. The compressor remains inoperative until the evaporator temperature rises to the preset temperature, at which time the switch closes and compressor operation resumes.

A pressure cycling switch is electrically connected in series with the compressor electromagnetic clutch. Like the thermostatic switch, the turning on and off of the pressure cycling switch controls the operation of the compressor.

The low-pressure cutoff or discharge pressure switch is located on the low side of the system and senses any low-pressure conditions. It is tied into the compressor clutch circuit, allowing it to immediately disengage the clutch when the pressure falls too low.

The electronic cycling clutch switch (ECCS) prevents evaporator freeze-up by sending a signal to the engine control computer. The computer, in turn, cycles the compressor on and off by monitoring suction line temperature. If the temperature gets too low, the ECCS will open the input circuit to the computer, which causes the A/C clutch relay to open, which disengages the compressor clutch. Often this switch is the thermostatic switch at the evaporator.

The high-pressure relief valve is used to keep system pressures from reaching a point that may cause compressor lockup or other component damage because of excessive high pressures. When system pressures exceed a predetermined point, the pressure relief valve opens, reducing the system's pressure.

The A/C high-pressure switch is used for additional A/C system pressure control. It is normally closed and its high-pressure contacts open at a predetermined A/C pressure. This results in the A/C turning off, preventing the A/C pressure from rising to a level that would open the A/C high-pressure relief valve. The A/C pressure transducer sensor is located in the high-pressure (discharge) side of the A/C system. The ACP transducer sensor provides a voltage signal to the PCM that is proportional to the A/C pressure. The PCM uses this information for A/C clutch control, fan control, and idle speed control.

The evaporator temperature sensor measures the temperature of the cool air immediately after the evaporator. This input to the A/C control module is used to detect evaporator freeze-up.

Hoses and Fittings

Although total hose replacement is the preferred way to correct for a hose leak, there are several accepted ways to repair refrigerant hoses and fittings. Using insert barb fittings and a length of replacement hose, you can fabricate an acceptable replacement for an original equipment hose. Insert barb fittings can also be used to replace bad original fittings or to replace a section of a hose.

When using an insert barb fitting **(Figure 55–31)** to replace a bad original fitting, the original fitting must be removed without damaging too much of the hose. Remove the hose from the vehicle. Set the

PROCEDURE

To check the various control devices, follow these steps:

STEP 1 Using the service information, locate the various pressure and temperature sensors in the system that controls the operation of the compressor.

STEP 2 Check the information to determine if each of these is normally closed or normally open.

STEP 3 Checking one sensor at a time, complete the following steps:

a. Disconnect the wires at the sensor or switch.

b. Connect the DMM across the switch terminals **(Figure 55–29)**.

c. Set the meter for resistance or continuity checks. If the switch is normally closed, the reading should be 0 ohms. If the switch is normally open, you should get an infinite reading. Any reading other than these is an indication of a faulty switch.

STEP 4 If a switch needs to be replaced, the system may need to be discharged. Check the service information before proceeding. Some systems have a Schrader-type disconnect below the switch. Switch replacement in these systems does not require system evacuation.

STEP 5 To remove the defective switch, loosen it and remove it.

STEP 6 To install the new switch, carefully thread it into place and tighten it. Then reconnect the wires leading to the switches.

FIGURE 55–29 All sensors and switches can be checked with an ohmmeter.

PROCEDURE

To fabricate a replacement A/C pressure hose, follow these steps:

STEP 1 Measure and mark the required length of replacement high-pressure hose.

STEP 2 Using the razor blade, cut the hose to the desired length. Make sure the cut is square and flat.

STEP 3 Apply clean refrigerant oil to the inside of the hose.

STEP 4 Install the correct ferrule onto the end of the hose.

STEP 5 Carefully inspect the new fitting to make sure it is free of nicks and other damage.

STEP 6 Coat the fitting with refrigerant oil and insert it into the hose.

STEP 7 Using the crimping tool designed for the ferrule, crimp the ferrule **(Figure 55–30)**.

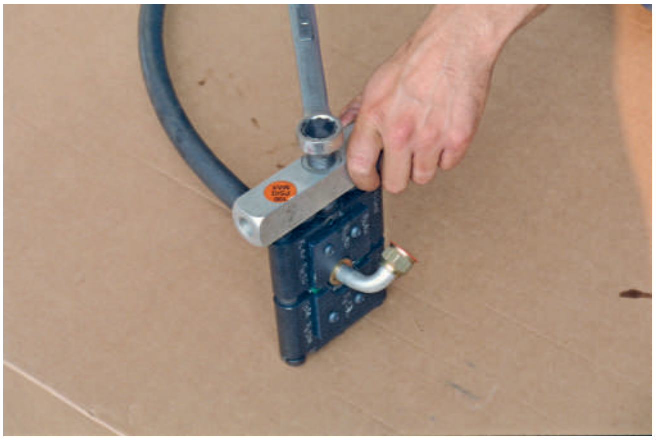

FIGURE 55–30 The ferrule is crimped with a special crimping tool.

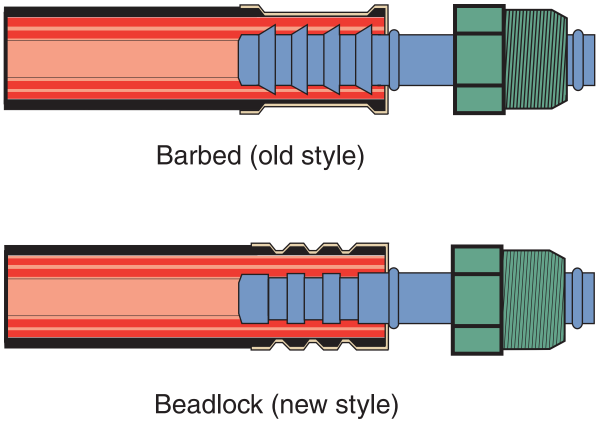

FIGURE 55–31 A comparison of a barbed fitting and the new-style beadlock fitting.

hose in a vise while cutting through the fitting's ferrule with a hacksaw. Make this cut in the direction of the hose, not through the hose. With the ferrule cut, use pliers to peel or pull the ferrule off. Cut the hose at a point just beyond the insert of the original fitting. Make sure the cut is square and flat. Apply clean refrigerant oil to the inside of the hose and to the fitting's insert. Insert the fitting into the hose. Position the hose clamp over the barb closest to the fitting before tightening it.

If the hose or line has spring lock fittings, a special tool is required to separate the sections. Put the tool over the coupling. Close the tool and push the lines into the tool to release the female fitting from the garter spring of the coupling. Then pull the male and female fittings apart. Remove the tool. When joining two fittings with a spring lock coupling, lubricate new O-rings and put them in their proper location on the male fitting. Insert the male fitting into the female fitting. Firmly push them together until they are secured by the spring lock coupling.

Rigid Line Repair Like pressure hoses, solid or rigid refrigeration lines are replaced rather than repaired if they leak. However, repairs can be made with special collars **(Figure 55–32)** inserted into the line to correct a kink or leak. The damaged section of the tube is cleanly cut out. The collar or fitting is inserted into the line after sealant has been applied to it. Using a special tool, the collar is pressed into the ends of the existing line **(Figure 55–33)**. The line is then crimped around the insert. This provides for a permanent seal.

Receiver-Dryer/Accumulator

The receiver-dryer/accumulator is often neglected when the A/C system is serviced or repaired. Failure to replace it can lead to poor system performance or replacement part failure. It is recommended that the receiver-dryer/accumulator and/or its desiccant be changed whenever a component is replaced, the system has lost the refrigerant charge, or the system has been open to the atmosphere for any length of time.

The desiccant draws moisture like a magnet and it can become contaminated in less than 5 minutes

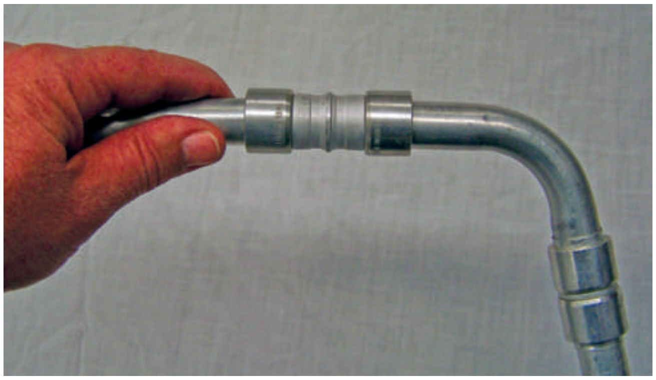

FIGURE 55–32 Repairs to rigid lines can be made with special collars.

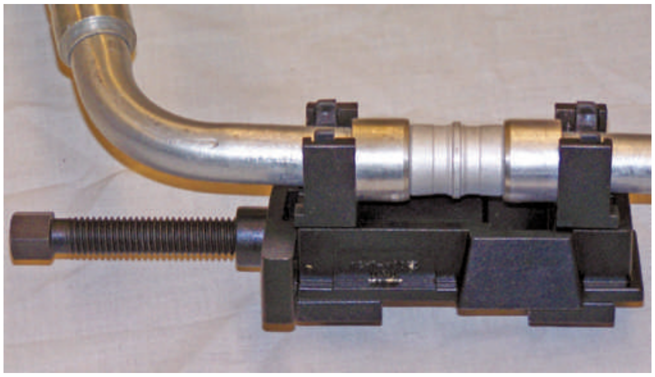

FIGURE 55–33 A designated tool is used to press the collar into the tube.

if it is exposed to the atmosphere. Keep it sealed. To replace a receiver-dryer/accumulator, disconnect the electrical connector to the low-pressure switch, if there is one. Then disconnect the inlet and outlet hoses or lines at the receiver-dryer/accumulator. Remove the mounting bolts and brackets from the receiver-dryer/accumulator and lift it out. The procedure for installation is the reverse of removal.

Accumulator Most late-model systems do not have a receiver/dryer; rather, they use an accumulator. The accumulator is connected to the low side at the outlet of the evaporator. The accumulator also contains a desiccant and is designed to store excess refrigerant and to filter and dry the refrigerant. If liquid refrigerant flows out of the evaporator, it will be collected by and stored in the accumulator. An accumulator/dryer should be replaced if there is excessive moisture or debris in the A/C system or when the accumulator leaks. To replace an accumulator, disconnect the lines at the accumulator's inlet and outlet fittings. Then loosen and/or remove the accumulator mounting bolts or screws. Lift the accumulator out. The procedure for installation is the reverse of removal. As soon as the accumulator is installed, immediately evacuate the system.

Evaporator

The evaporator and its controls often need service. If the evaporator is clogged, leaking, or damaged, it should be replaced. As vehicles make the switch from R-134a to R-1234yf, some vehicles from a manufacturer may use one refrigerant while other vehicles from the same manufacturer use the other. For R-1234yf vehicles, the evaporators are reinforced and stronger than those used in R-134a systems, but may not look any different. It is important that if replacing an evaporator on a R-1234yf vehicle that the correct part is installed.

Evaporator Water Drain Because the evaporator is also responsible for controlling the humidity in the vehicle, a check of its drain is necessary. This is especially true if the customer had concerns about odor or water on the carpet. To check the drain, raise the vehicle on a lift. Locate the evaporator case drain tube. Place the drain pan under the evaporator case. Disconnect the tube from the case. If no water comes out, carefully clean out the drain hole and tube at the evaporator case. You may need to insert a rod through the tube to clean it out; do this carefully because the

STEP 1 Recover the refrigerant using an approved recovery/recycling equipment.

STEP 2 Disconnect the negative battery cable, if specified in the service information.

STEP 3 If the evaporator and heater core are a combined unit, drain the engine's coolant.

STEP 4 Disconnect and label all electrical connectors, cables, and vacuum hoses that are connected to the evaporator.

STEP 5 Disconnect the refrigerant hoses at the evaporator and plug or cap the hose ends to prevent dirt and moisture from entering the system.

STEP 6 Unbolt and remove the evaporator.

STEP 7 Drain the oil from the evaporator into a graduated container. Record the amount of oil removed.

STEP 8 Check the oil for dirt. If the oil is contaminated, replace the accumulator or receiver/dryer.

STEP 9 Add the same amount of new refrigerant oil as was drained out or the amount specified in the service information to the new evaporator.

STEP 10 Coat the new O-rings for the evaporator and the line fittings on the evaporator with clean refrigerant oil.

STEP 11 Install the new evaporator and tighten the fittings. Also install a new receiver-dryer/accumulator or its desiccant bag.

STEP 12 Immediately evacuate the system.

STEP 13 Reinstall and reconnect all parts, wires, cables, and vacuum hoses that were disconnected during removal. Add coolant if needed.

STEP 14 Connect the negative battery cable.

STEP 15 Evacuate and recharge the system.

STEP 16 Perform a leak test and correct any problems.

tube is accordion shaped and one of its bends may feel like a restriction. If no water comes out while trying to clear the tube, the entire evaporator case must be cleared. If water comes out of the case, the outside drain tube should be cleared by inserting the air nozzle into an end of the tube. Low air pressure should remove any restrictions in the tube.

Odor Control

Because the evaporator becomes wet from condensed water vapor, odor from mildew buildup in the evaporator case or on the evaporator itself is a common concern. To reduce odors, manufacturers and the aftermarket supply disinfecting kits to clean the evaporator. When performing a cleaning of the evaporator, refer to the manufacturer's service information for the proper disinfectant and procedures. In general, you will need to apply the disinfectant directly onto the evaporator and allow the chemicals to work on the surface and then rinse it with clean water.

Expansion Devices Basically there are two types of expansion devices. To replace an orifice tube assembly, always use the tools and procedures recommended by the manufacturer. Begin by disconnecting the inlet line at the evaporator. Then pour a small amount of clean refrigerant oil into the orifice tube. Insert the orifice removal tool. Turn the handle of the tool just enough for it to engage onto the tabs of the orifice tube. Hold the handle of the tool in position while turning the tool's outer sleeve clockwise to remove the orifice tube **(Figure 55–34)**. Coat the new orifice tube with clean refrigerant oil. Place

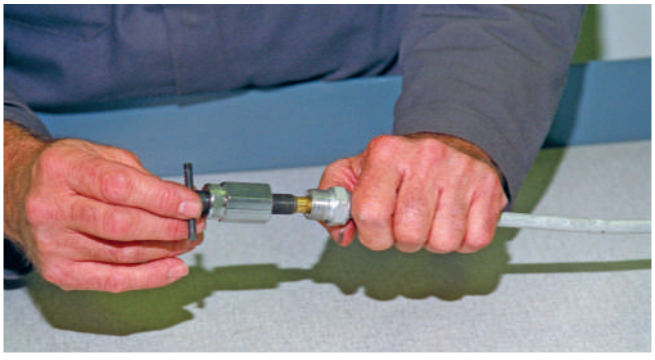

FIGURE 55–34 The tool designed to remove and replace an orifice tube.

Caution! Always wear safety goggles when working with refrigerant containers or servicing A/C systems.

FIGURE 55–35 Always install a new O-ring when replacing an orifice tube.

it into the evaporator line inlet. Push it in until it stops. Install a new O-ring on the refrigerant line **(Figure 55–35)** and reconnect it.

To replace a thermostatic expansion valve or H-block, disconnect the inlet and outlet lines at the TXV. Then remove whatever is used to keep the remote sensing bulb secure. Loosen and/or remove the mounting clamp for the TXV and remove the TXV from the evaporator. The procedure for installation is the reverse of removal.

Condenser

The condenser is quite reliable and only needs replacement when there are leaks due to damage. On many vehicles, the radiator, cooling fan, and/or shroud must be removed to gain access to the condenser. If the radiator must be removed, drain the coolant. Disconnect and label all electrical connectors that are connected to the condenser and all those that may be in the way. Disconnect the refrigerant hoses at the condenser and plug or cap the hose ends to prevent dirt and moisture from entering the system. Unbolt and remove the condenser. If the receiver-dryer/accumulator mounts to the condenser, disconnect it and remove it with the condenser. Drain and measure the oil from the condenser into a graduated container. Check the oil for dirt and debris. If the oil is contaminated with moisture, replace the accumulator or receiver/dryer. Add the above amount of new refrigerant oil or the amount specified in the service information to the new condenser. Install the new condenser and loosely tighten the mounting bolts. Coat the new O-rings for the condenser and the line fittings on the condenser with clean refrigerant oil. Tighten the fittings, and then tighten the mounting bolts. Then immediately

evacuate the system. Reinstall and reconnect all parts, wires, cables, and vacuum hoses that were disconnected or removed during removal. Connect the negative battery cable. Check for coolant and refrigerant leaks.

Recharging the System

All of the refrigerant in the system must be recovered prior to evacuation. Evacuation is the name given to the process that pulls all traces of air and moisture from the system. This is done by creating a vacuum in the system **(Figure 55–36)**. A vacuum pump is connected to the system to do this. The vacuum pump should remain on and connected to the system for at least 30 minutes after 26 to 29 inches of mercury (in. Hg) is reached.

Any air or moisture that is left inside an A/C system reduces the system's efficiency and eventually leads to major problems, such as compressor failure.

Air causes excessive pressure within the system, restricting the refrigerant's ability to change its state from gas to liquid within the refrigeration cycle, which drastically reduces its heat absorbing and transferring ability. Moisture, on the other hand, can cause freeze-up at the orifice tube or expansion valve, which restricts refrigerant flow or blocks it completely. Both of these problems result in intermittent cooling or no cooling at all. Moisture mixed with R-134a forms hydrochloric acid, causing internal corrosion, which is especially dangerous to the compressor. The vacuum pump reduces system pressure, vaporizes the moisture, and then exhausts it with the air.

The main responsibility of the vacuum pump is to remove the contaminating air and moisture from the system. The vacuum pump reduces system pressure in order to vaporize the moisture and then exhausts the vapor along with all remaining air. The pump's ability to clean the system is directly related to its ability to reduce pressure—create a vacuum—low enough to boil off all the contaminating moisture. As the vacuum (negative pressure) in the system reaches 29 in. Hg, the boiling point of the moisture in the system approaches room temperature. As the pressure is further reduced, the moisture will boil at even lower temperatures. Between 29 and 29.8 in. Hg, the boiling point drops to about 32 °F (0 °C).

An electronic thermistor vacuum gauge is designed to work with the vacuum pump to measure the last, most critical inch of mercury during evacuation. It constantly monitors and visually indicates the vacuum level so you know when the system has a full vacuum and will be moisture free. After the system is evacuated, it can be recharged. If the system will not pull down to a good vacuum, there is probably a leak somewhere in the system. Photo Sequence 51 goes through a common way to evacuate and recharge a system.

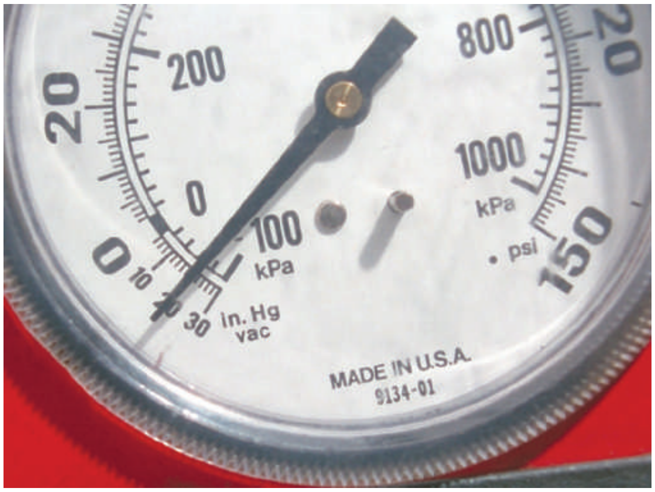

FIGURE 55–36 The reading on a low-pressure gauge with a vacuum pump connected to an A/C system through a gauge set.

Caution! Always wear safety goggles and protective gloves when handling disinfectants and cleaning the system.

Charging

Refilling the system with refrigerant is called charging the system. Refrigerant is added through the system's service ports **(Figure 55–37)**. Depending on the method and source of new refrigerant, refrigerant is introduced through the low or high side of the system. When the system is operating, refrigerant is charged through the low side. On some vehicles with the system off, charging is done through the high side. Always refer to the service information for the correct procedure.

Currently, the only approved way to charge R-1234yf systems is by a Section 609 certified technician using a R-1234yf RRR unit. Because R-1234yf poses a flammability hazard, even a slight one, the proper equipment must be used. In addition, as of late 2017, the cost of R-1234yf is quite high, around $100 per pound. Shops need to closely track the

P51-5 Activate the reclaimer to discharge the system, then begin evacuation. Allow enough time for the machine to draw a good vacuum (at least 29 in. Hg) in the system. Observe the gauge set to determine when a vacuum is created.

P51-6 Close the valves at the gauge set and disconnect the reclaiming machine. Connect the charging station and open the gauge set valves. Set the unit to deliver the required amount of refrigerant for that system.

use of the refrigerant since if even small amounts escape, the cost can quickly be significant.

Because late-model vehicles require less refrigerant than in the past, modern recharging equipment must be more accurate in dispensing the amount of charge. New charging stations must meet the SAE J2788 standard, which requires an accuracy of 0.5 oz. This helps prevent overcharging, which can degrade system performance and cause damage to the system.

Always use the same type of refrigerant and refrigerant oil for the system. The importance of the correct charge cannot be stressed enough. The efficient operation of the A/C system greatly depends on the correct amount of refrigerant in the system. A low charge results in inadequate cooling under high heat loads due to a lack of reserve refrigerant and can cause the clutch cycling switch to cycle faster than normal. An overcharge can cause inadequate cooling because of a high liquid refrigerant level in the condenser. Refrigerant controls will not operate properly and compressor damage can result. In general, an overcharge of refrigerant will cause higher-than-normal gauge readings and noisy compressor operation.

The charging cylinder is designed to meter out a desired amount of a specific refrigerant by weight. Compensation for temperature variations is accomplished by reading the pressure on the gauge of the cylinder and dialing the plastic shroud. The calibrated chart on the shroud contains corresponding pressure readings for the refrigerant being used.

When charging an A/C system with refrigerant, the pressure in the system often reaches a point at which it is equal to the pressure in the cylinder from which the system is being charged. To get more refrigerant into the system to complete the charge, heat must be applied to the cylinder.

The A/C system may only be charged through the high side with the system off **(Figure 55–38)**. Inverting the refrigerant container disperses liquid refrigerant. As a general practice, the system is vapor charged through the low side while the system is running. If the system is charged through the high side (with the system off), the compressor should be turned a few times by hand afterward to ensure there is no liquid refrigerant on top of the piston. If liquid refrigerant enters the compressor, this component may be damaged. The vehicle should always be charged from the low-pressure side if the engine is on. If the engine is off, it can be charged from the high-pressure side.

Never open the high-side hand valve with the system operating and a refrigerant can connected to the center hose. The refrigerant will flow out of the system under high pressure into the can. High-side pressure is between 150 and 300 psi and will cause the refrigerant tank to burst. The only occasion for opening both hand valves at the same time would be when evacuating the system or when reclaiming refrigerant with the system off.

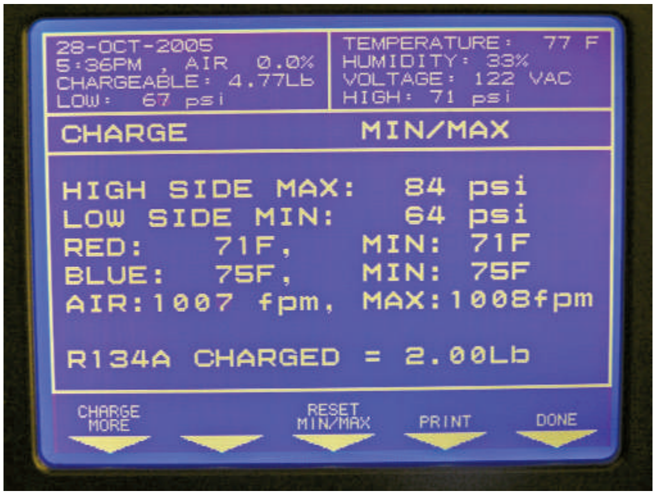

FIGURE 55-38 The recharging equipment will display how much refrigerant was added to the system.

Charging Cylinder

With an increase in temperature in any cylinder filled with refrigerant, there is a corresponding increase in pressure and a change in the volume of liquid refrigerant in the cylinder. To measure an accurate charge according to the weight of a cylinder, it is absolutely necessary to compensate for liquid volume variations caused by temperature variations. These temperature variations are directly related to pressure variations and accurate measurements by weight can be calibrated in relation to pressure.

The charging cylinder is designed to meter out a desired amount of a specific refrigerant by weight. Compensation for temperature variations is accomplished by reading the pressure on the gauge of the cylinder. A calibrated chart on the machine contains the corresponding pressure readings for the refrigerant being used.

When charging an A/C system with refrigerant, the pressure in the system often reaches a point at which it is equal to the pressure in the cylinder from which the system is being charged. To get more refrigerant into the system to complete the charge, the cylinder can be placed on a heating plate.

Testing for Noncondensable Gases Whenever using recycled refrigerant, it should be checked for noncondensable gases. Install a calibrated pressure gauge on the container and measure the pressure in the container. Measure the temperature of the air 4 inches away from the container's surface. Compare the measured pressure and temperature to the manufacturer's pressure/temperature chart. Determine if the recycled refrigerant has excessive noncondensable gases. If the refrigerant has excessive noncondensable gases, it should be recycled again and then retested before it is used.

Recover/Recycling/Recharging Station Maintenance

Even though modern charging stations are very dependable, most require some routine maintenance to keep in good working condition. Most systems have replaceable filters that need to be changed after a certain amount of refrigerant filtration, often after 220–331 pounds (100–150 kg). Place the machine into Filter Service mode or equivalent to evacuate the internal hoses. Remove the filter(s) **(Figure 55–39)** and replace with ones specified by the manufacturer of the unit. If the machine has a refrigerant identifier, there is likely a separate filter, oxygen sensor, and sample hose that needs to be replaced. Replace these items as per the machine's maintenance schedule or when changing the refrigerant filter.

To check the calibration of the tank scale, put the machine into Scale Calibration mode. Next, place the calibration weight on the scale and the machine will self-calibrate. This helps to ensure the machine is charging using the correct amount of refrigerant.

To keep the vacuum pump operating correctly, the pump oil should be changed after a certain number of hours of use. Locate the pump drain plug and drain the oil into a suitable container. Dispose of the oil with other waste refrigerant oil products. Pour in the specified amount of new pump oil. Contaminated pump oil can shorten the life of the pump and cause permanent damage if not maintained.

Climate Control Systems

When diagnosing climate control systems, it is essential to have accurate information about the system before beginning. This information can be obtained from a number of sources: manufacturer service manuals, manufacturer service information, websites, Internet-based information systems, technical service bulletins, and aftermarket electronic and printed manuals.

Self-Diagnosis

Most climate control systems are computer controlled and have a self-diagnostic feature. Manufacturers' specifications must be followed to identify the malfunction display codes, because they differ from car to car. To check the system, refer to the service information and determine if the automatic climate control system relies on the PCM, BCM, or a separate computer for control. Modern systems are part of CAN therefore DTCs and other data are available through a scan tool. Typically, system pressures and input and output data are also available **(Figure 55–40)**. In addition, active command of system operation, such as blend doors and blower speed is often possible. By using active commands or bidirectional control, you can determine if a component and its circuit are functioning.

If the unit is part of the PCM/BCM system, connect the scan tool and retrieve any codes that may be present. If the unit is controlled by its own computer system, use your service information and the procedure for retrieving trouble codes. If the system is a semiautomatic system, check the service information for the proper diagnostic procedures for checking evaporator and heating controls. Test the components or subsystems identified by the trouble codes.

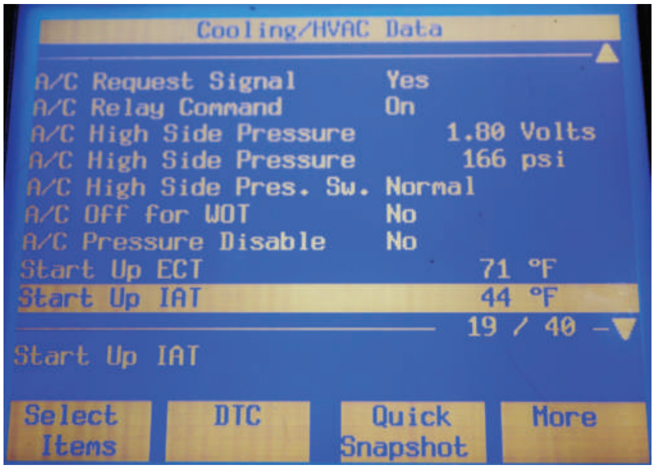

FIGURE 55–40 Using scanner data to monitor A/C system operation.

The DTCs from the system can lead a technician to the following problems:

- An open or short in the air mix control motor circuit
- A problem with the air mix control linkage, door, or motor circuit
- An open or short in the mode control circuit
- A problem with the mode control linkage, doors, or motor circuit
- A problem in the blower motor circuit
- A problem with the HVAC control unit
- An open or short in the evaporator temperature sensor circuit
- A problem with temperature and sunload sensors

Some automatic temperature control systems allow for testing through the control panel. By pressing and holding two buttons, such as the AUTO and Recirc buttons at the same time, the control panel will enter a self-diagnostic mode. During this mode, the system will move through different output modes, such as full heating to full cooling. Once completed, trouble codes are displayed on the control panel. Because each system is different, you will need to refer to the manufacturer's service information for procedures specific to the vehicle.

Blower Motor

The blower motor is usually located in the heater housing assembly. It ensures that air is circulated through the system. Its speed is controlled by a multi-position switch in the control panel. The switch works in connection with a resistor block that is usually located on the heater housing. Vehicles with automatic climate control typically use a blower speed control module, which uses pulse-width modulation to control motor speed.

On some vehicles, when the engine is running, the blower motor is in constant operation at low speed. On automatic temperature control systems, the blower motor is activated only when the engine reaches a predetermined temperature. The blower motor circuit is protected by a fuse located in the fuse panel. The fuse rating is usually 20 to 30 amperes.

The blower motor resistor block is used to control the blower motor speed. The typical resistor block is composed of three- or four-resistors in

series with the blower motor, which control its voltage and current. The speed of the motor is determined by the control panel switch, which puts the resistors in series. Increasing the resistance in the system slows the blower speed.

If the blower does not operate, use a testlight to make sure there is voltage on both sides of the fuse. Check the wiring diagram and identify whether the blower circuit is controlled by a ground side switch or an insulated (power side) switch. If the ground side of the circuit is controlled, check to see if voltage is arriving at the motor. On cars where the blower motor is behind the inner fender shell, hunt out the wiring and check for voltage. If the blower motor is getting voltage, the problem is either a burned-out blower motor or an open ground in the motor circuit. In situations where no voltage is available at the motor, backtrack to check for an open. Check also for burned or corroded connections in the blower relays and connectors. An open blower motor ground would cause the motor not to run at all. If the correct amount of voltage is available to the motor and the ground is good, suspect a bad motor.

If the blower works at some speeds but not all, check the voltage to the blower motor at the various switch positions. If the voltage does not change when a new position is selected, check the circuit from the switch to the resistor block. If there was zero voltage in a switch position, check for an open in the resistor block. Refer to **Table 55–1** for blower motor diagnosis.

If the motor runs when it should not, there is probably a short in the circuit. If a ground side switch controls the circuit, check for a short to ground in the control circuit. The exact problem can be isolated by disconnecting portions of the circuit until the motor stops. The short is in that part of the circuit that was disconnected last. If the circuit is controlled by an insulated switch, check for a wire-to-wire short. Check other circuits of the vehicle to identify what circuit is involved in this problem. That circuit will also experience a lack of control, or when that circuit is turned off, the blower motor will turn off. The exact problem can be isolated by disconnecting portions of the circuit until the motor stops. The short is in that part of the circuit that was disconnected last.

To diagnose PWM blower motor control systems, begin by setting the system to where the blower should operate. If the blower does not work at all, refer to the manufacturer's service information to determine how to access the self-diagnostics for the ATC system. In general, diagnosis of an ATC blower motor concern is similar to a non-ATC system. Determine if the motor is power or ground circuit controlled and test for power and ground at the motor. Verify which constant, either power or ground, is present. If the blower control circuit is intact, the motor is faulty.

If the PWM signal is not present at the motor you need to determine the cause. Using either the self-diagnostic function or a scan tool, determine whether a blower motor request is received and if the control module is attempting to control blower motor speed. If the inputs are present and correct and the blower is commanded on but does not operate, look for an open in the wiring between the blower control and the motor.

Doors and Ductwork

To check the proper functioning of the ductwork, move the temperature control lever to see if any change occurs. If it does not, shut off the air conditioner and turn on the heater. Move the temperature control arm again to see if any change occurs. If not, check the cable and the flap door connected to the temperature control lever. You might be able to reach under the dash to reconnect the cable or free a stuck flap.

If no substantial airflow is coming out of the registers, check the fuses in the blower circuit. Remove

the fan switch and test it. Check the blower motor by hot-wiring it directly to the battery with jumper wires.

Controls

Most systems use electric motors to control the blend and mode doors; however, some use vacuum. To check these systems, identify and inspect the hoses and components for vacuum motors and doors. Look for disconnected or broken hoses, broken connectors, misrouted vacuum lines, and loose or disconnected electrical connectors at vacuum switches and controls. Identify the vacuum source for the various doors and switches of the duct system and make sure vacuum is available when the engine is running. Disconnect that vacuum source. Connect a vacuum gauge to the inlet for the defroster door motor(s) and record the vacuum available there when the master control switch is in the following positions: max, norm, bilevel, vent, heat, blend, defrost, and off.

If they do not move with the engine's vacuum, use a hand-operated vacuum pump to check the component's activity and its ability to hold a vacuum. Use the vacuum pump to check all one-way check valves. Also, check all mechanical or cable linkages and controls. Make sure the cables are properly attached to the levers of the control switch. If the cable(s) is equipped with an automatic adjuster, make sure the adjusting mechanism operates freely and is not damaged.

Control Panel At times the control unit is the root of problems **(Figure 55–41)**. Inspect the connectors to the control unit, look for damage and corrosion. For systems with mechanical switches, use an ohmmeter to check for continuity through the blower motor switch in all of its positions. Compare your results with the wiring diagram for the switch. Check the resistance across the temperature control switch. If the mode selector switch is electrical, check for continuity across the terminals as you move the switch through the various mode selections. If the mode selector switch is a vacuum switch, apply a vacuum to the inlet of the switch and feel for a vacuum at the various tube connectors on the switch while you move the selector through its various positions. Compare your results to the information in the service manual.

For systems with ATC or electronic controls, connect a scan tool to monitor the operation of the input switches **(Figure 55–42)**. ATC control panels are not repaired; rather, they are replaced as a unit. Care needs to be taken when handling and replacing these units. Like the other electronic circuits on a vehicle, the control panel may be part of the BCM circuit. Follow all precautions to eliminate static and voltage spikes at the BCM.

Solar Sensor

The solar sensor detects sunlight. It controls the climate control system on many vehicles. The output voltage from the sensor varies with the amount of sunlight. When the sunlight increases, the output voltage increases. As the sunlight decreases, the output voltage decreases. The sensor is monitored by the A/C control module. DTCs will indicate a perceived problem. The systems typically look for an open or short in the solar sensor circuit.

Three Cs: Concern, Cause, Correction

ALL TECH AUTOMOTIVE				REPAIR ORDER
Year: 2010	**Make:** Dodge	**Model:** Ram 1500	**Mileage:** 102,544	**RO:** 19301
Concern:	Customer states the air conditioning is not working properly. It sounds like the A/C turns on and off quickly.			
History:	Car had A/C system serviced and recharged 2 months ago.			
Upon starting the engine and turning on the A/C, the technician notices that the compressor turns on and off again rapidly. Thinking the system may be low on refrigerant, causing the low-pressure switch to open and turn the compressor off, she connects a gauge set to the system. With the compressor off, pressure is around 90 psi on the low and high sides, indicating normal pressure. Since the pressure indicates the system is not low on refrigerant, she turns the compressor on and watches the gauges. She immediately notices that the low-side pressure drops and the high-side pressure increases beyond normal to well over 400 psi before the compressor shuts off.				
Cause:	Inoperative A/C condenser fan allowing the A/C pressure to increase enough to open the high pressure cutoff switch.			
Correction:	Replaced fan and system operates normally.			

SUMMARY

- Air-conditioning (A/C) systems are extremely sensitive to moisture and dirt. Therefore, clean working conditions are extremely important. The smallest particle of foreign matter in an A/C system contaminates the refrigerant, causing rust, ice, or damage to the compressor.
- Air conditioner testing and servicing equipment includes a manifold gauge set, service valves, vacuum pumps, charging station, charging cylinder, recovery/recycling systems, and leak-detecting devices.
- Refrigerant evaporates quickly when it is exposed to the atmosphere. It will freeze anything it contacts. If liquid refrigerant gets in your eyes or on your skin, it can cause frostbite. Never rub your eyes or skin if refrigerant has contacted you. Immediately flush the exposed areas with cool water for 15 minutes and seek medical help.
- Never expose A/C system components to high temperatures. Heat will cause the refrigerant's pressure to increase. Never expose refrigerant to an open flame.
- Refrigerants should never be mixed. Their oils and desiccants are not compatible. If refrigerants are mixed, contamination will occur and may result in A/C system failure. Separate service equipment, including recovery/recycling machines and service gauges, should be used for the different refrigerants.
- The manifold gauge set is used when discharging, charging, and evacuating the system; it is also used for diagnosing trouble in the system. Because R-134a is not interchangeable with R-12, separate sets of hoses, gauges, and other equipment are required to service vehicles.
- Performance testing provides a measure of A/C system operating efficiency.
- A manifold pressure gauge set is used to determine both high and low pressures in the refrigeration system. The desired pressure readings will vary according to temperature.
- Using an electronic leak detector is the preferred method of leak detection.
- A common leak detection method includes a fluorescent dye and a black light glow gun to locate the source of leaks.
- All refrigerant must be discharged from the system before repair or replacement of any component, except for compressors with stem service valves.
- Recycling collects old refrigerant from the system being serviced and cleans it up and prepares it to be used in the future.

- R-12-based systems use mineral oil, whereas R-134a systems use synthetic polyalkylene glycol (PAG) oils. Using a mineral oil with R-134a will result in A/C compressor failure because of poor lubrication. Use only the oil specified for the system.
- While evacuating the system, the vacuum pump should remain on and connected to the system for at least 30 minutes after 26 to 29 inches of mercury is reached.
